When the last calcination is finished, the mixture of lime and ashes is carefully gathered up, and thrown into large vessels of water, and with every hundred weight of it, they put in one pound weight of kekio; they stir the whole together; and when the coarser part has subsided to the bottom, they take off the finer, which swims at the top in form of a fine cream, and putting it into another vessel of water, they let it subside to the bottom by long standing; they then pour off the water, and save the residuum in form of a thick oil.

This they mix with the oil of stone, prepared by powdering and washing in the same manner a particular sort of

of flones, and with this they cover all the vessels that they intend to varnish. The *ferri* have a very great share in the advantage that this oil has over our common varnishes; and the Chinese tell us, that they once instead of *ferri* used the wood of a tree, called *le-ti*, and they suppose that the superiority of the old porcelain over the present, is owing to the use of this tree instead of the *ferri*, but it is now too scarce among them. The new manufacture which we have at Bristol, excels every thing that has been done of the like kind, in the beauty of the varnishing; and it is said, they have founded their advantage on an imitation of this and the Chinese oil of flones. These two oils, as they are called, are always mixed together; and they must be carefully preserved of the same degree of thickness, or else all the varnishing will not be even.

FERN, flowering. See **OSMOND REED.**

FERN, common, or true male. See **MILT-WOOL.**

FERN, dwarf, in Botany, the name of a genus of plants, the characters of which are these: the flowers are not discovered; the seeds grow in clusters on the backs of the leaves, and the whole plant resembles the larger of common ferns.

FERN, male, or moss. See **HIMANTIS.**

FERN, fawn. See **CHEVIL.**

FERNAMBUC. See **DRACIL WOOD.**

FEROENSIS Marga, in Natural History, a name given by some authors, to a mallee earth, found principally in the fissures and cavities of flones, and called by the generality of later naturalists, *argilla micacea* and *terre lene*; and by the ancients, *terra, or creta flosculosa*. See **LAC LUNA.**

FERRA, in Ichthyology, the name of a fish, called also by some *gambal* or *GUINAD*.

FERRARIA, in Botany, a genus of the *syndesmon triandria* class. Its characters are these: the flower is inclosed in a double spathe or sheath, out of each of which is produced one flower; the flower has six oblong acute-pointed petals, three of which are alternately longer than the other, and they seem to be joined at their tails; their borders are fringed, turned backward, and silky. It has three filaments which rise above the petals, and a roundish three-cornered germ situated under the flower, which afterward turns to an oblong smooth three-cornered capsule, crowned by the decayed petals of the flower; with three cells, wrapped in the permanent sheath of the flower; in each cell are lodged many small round seeds. There are two species, natives of the Cape of Good Hope. There is a great singularity in the root of one of these species, that it vegetates only every other year, and sometimes every three years: in the intermediate time it remains inactive, though very found and good. Miller.

FERRARIA is also a name used by some authors for *agrimony*; and by others, in particular by Lohel, for the *scrophularia* or *fig-wort*.

FERRER, Ferrera, in Zoology, an animal of the **MUSTELA** or **WEASEL** kind, called by some also **MUSTELA fuscata**, **FURGO**, and **FUSCULUS**.

It is of a middle size, between the weasel and polecat; its head is small and flatish; its ears short, erect, and very wide; its nose or snout long, like that of a fox; and its eyes small and red; its colour is a pale yellowish white; the back and sides a little darker than the belly; and its feet have all five claws each; it breeds very well with us, but is said not to be a native here, but brought from Africa. Ray's Syn. Quad. p. 196.

It was originally brought from Africa into Spain, in order to free that country from the multitude of rabbits with which it was over-run; and from thence the rest of Europe was supplied with it.

This creature has but one note in her voice, which is a shrill, but small whining cry. The female usually brings forth seven or eight young ones at a time; she carries them in her body forty days, the young ones are blind for a long time after they are hatched. When they are reared, they are to be fed with milk, and with barley-bread; they will fall a long time; when they walk they set up their back which is otherwise so long that it would be troublesome to drag it out, when they are touched, they smell very disagreeably; they naturally sleep very much. The *ferret* is a bold and voracious animal, and is an enemy to almost all others. It does not eat the flesh of the creatures it kills, but sucks their blood. The use we make of this creature is the feeding it into rabbit-holes to drive them out; but we are obliged to fasten up their mouths that they may not tear the rabbits to pieces; but it still is able to annoy them with its claws, and soon drives them out. It feeds on milk, small birds, and the flesh of animals, and is a creature easily kept tame, and will breed and bring up its young in that state; and these will naturally hunt the rabbit in the same manner as their parents.

Vol. II. N° 127.

When the warrener has occasion to use the *ferrets* to catch rabbits, he fast makes a noise in the warren to frighten them all into their holes; then he pitches his nets; and having muzzled the *ferrets*, that he may not bite the rabbits, he turns him into their holes to frighten them out; and then the dogs drive them into the nets that are set for them. Warreners assert, that the *ferret* will mix with the *ferret*; and they are sometimes obliged to procure an intercourse between these animals to improve the breed of the latter, which, by long confinement, becomes less eager after rabbits, and less useful; Buffon denies this; but Mr. Pennant alleges a fact in proof of it. Zoology, vol. i. p. 91.

FERRAT, Indian, uterine flone, a name by which some have called the animal known in America by the name of **QUIPPELE** and **QUIL**. See **ICHNEUMON.**

FERRERS, in Glass-making, the iron with which the workman tries the most metal to see if it be fit to work.

It is also used for those iron which make the ring at the neck of bottles.

FERRITES d'Epagne, in Natural History, a name given by authors to certain flones of a regular figure, found on the sides of a rock in Spain; and as has been since discovered very plentifully on the bottom and sides of the Fontaine de Salut, near Bagneres in France, and in other places in the country thereabout. They are small flones of the colour of rusty iron, and of a regular figure, being either parallelepiped with oblique angles, of which the sides are unequal, or small solid bodies with six sides, only differing from cubes or dice in this, that the surfaces are not perfectly perpendicular to one another, but a little inclined; they are also commonly longer than they are broad, and broader than they are high. The largest of these fall short of an inch in measure, being about eleven lines in length, nine and a half in breadth, and six in height; but they are usually a great deal smaller, and are sometimes found in clusters, a hundred or more together; and some of them have shining films, seemingly of a metallic substance. These flones are not only found in the bath, but in the digging of a way for a common road from the town of Bagneres to it, they were found lodged in their proper stratum. The workmen here met with a bed of a soft kind of slate of a bluish colour, but lighter than that of the common slate. The whole rock they worked through was composed of layers or beds of this, lying almost parallel over one another. The substance of the slate seemed to be a composition of fibres or strings laid regularly side by side by one another, and all equally inclined to their beds or layers. Whence it comes, that upon breaking them with a hammer, the pieces sometimes are pretty like the figure of a regular parallelepiped with oblique angles. Upon a narrower examination of this sort of slate, there are usually found in it a great number of parallelepiped flones like those before spoken of, only smaller; and several little black spots discovered in other parts of the flone when they are examined with glasses, prove also to be regularly figured bodies of the same kind.

Every one of these flones, so long as it remains in the rock, is always found between two bundles or clusters of transparent fibres, of which generally one is placed on the one, and the other on the opposite side; these clusters of fibres are largest in the largest flones; however, they are always found even about the smallest in some quantity. Philoz. Trans. N° 477. p. 32.

FERRITICO, in the Glass-trade, a substance which serves to colour glass. This is made by a simple calcination of copper, but it serves for several colours. There are two ways of making this; the first is as follows: take thin plates of copper, and lay them on a layer of powdered brimstone, in the bottom of a crucible; over these lay more brimstone, and over that another layer of the plates, and so on alternately till the pot is full. Cover the pot, put it well, place it in a wind furnace, and make a strong fire about it for two hours. When it is taken out and cooled, the copper will be found so calcined that it may be enscribed to pieces between the fingers like a friable earth; it will be of a reddish, and in some parts a blackish colour. This must be powdered and sifted fine for use. Neri's Art of Glass, p. 30.

The other way is less easy, but it makes a more valuable *ferrete*. It is this: make a number of stratifications of plates of copper and powdered vitriol alternately in a crucible, which place on the floor of the glass-furnace near the eye, and let it stand there three days; then take it out, and make a new stratification with more fresh vitriol, and calcine it again as before; repeat this operation six times, and a most valuable *ferrete* is produced.

FERRIFIC Clay, a term used by some writers to express that principle to which what they call the production or generation of iron in burnt-bodies, in which no iron could be discovered before burning, is owing. It is the

general opinion of the present philosophers, that this iron thus discovered in the ashes of plants, and the like burnt substances, really existed there before, and only needed the diffusion of the concreted body to the bringing of its parts together. If this be the case, there is evidently no production of iron in the case, and therefore the term *ferric* is a word without meaning. Becher, however, in his Supplement to his *Physica Subterranea*, is of a very different opinion, determining, that the iron is really produced in these cases during the action of the fire; and that by the transmutation of some other matter into iron; and from this he argues the possibility of gold-making among chemists by transmuting something else into gold, so some other substance is in this case transmutated into iron.

FERRUGINOUS, denotes a thing to partake of the nature of iron, or to contain particles of that metal.

It is particularly applied to certain mineral springs, whose water in their passage along the strata of the earth meets with the ore of this metal, or with pyrites containing it, part of which they wash off, and carry with them; and thus become impregnated with the principles thereof. Such are what we call *CHALYBEATE WATERS*.

The waters of Tunbridge, those of Forges, and of the iron spring at Bourges, and many others, are *ferrugineous*.

FERRUGO, the rust of IRON, or a kind of cake found on the surface thereof.

The rust of iron is a refrigerant; applied by way of pessary, it rectifies the flux uterinus, and drank, prevents conception: it cures the erysipelas, and exanthematous eruptions. It is of good use in a paronychia, roughness of the eye lids, and a candeloma. It also strengthens the gums, relieves under the gout, being rubbed on the part affected, and makes the hair grow after an alopecia. Wine or water, in which red hot iron has been quenched, being drank, is good for the colic passion, dysentery, disorders of the spleen, cholera morbus, and relaxations of the stomach.

FERRUM. See IRON.

FERRUM spinosum. See *Horse-foot VETCH*.

FERRY, a liberty by prescription of the King's grant to have a boat for passage upon a river, for the carriage of horses and men for a reasonable toll: it is usually to cross a large river. *Termes de Ley*.

A *ferry* is no more than a common highway; and no action will lie for one's being disturbed in his passage, unless he allege some particular damage, &c. 3 Mod. Rep. 204. The not keeping up of a *ferry* has been held to be indictable.

FERTILITY, FRUITFULNESS, that quality which denominated a thing fertile or prolific.

The Egyptian nitre or natron renders the ground exceedingly fertile. M. de la Chambre observes, that the plants grow in such abundance in Egypt, that they would choke one another if they were not hindered by throwing sand upon the fields, inasmuch that the Egyptians milk the soil so much point to lessen the richness of their soil as other nations do to increase that of theirs. Phil. Transact. No. 160.

Nothing can produce *fertility* in either sex but what promotes perfect health; nothing but good blood, spirits, and perfect animal functions, that is, high health, can beget perfect *fertility*; and therefore, according to Dr. Cheyne, all means and medicines, all nostrums and specifics to procure *fertility*, different from those which procure good blood and spirits, are almost quackery and cheating. He says, that water-drinking males are very rarely fertile; and that if any thing in nature can prevent *fertility*, and bring fine children, it is a milk and seed-diet, persevered in by both parents.

FERULA, a little wooden pallet or slice, reputed the schoolmasters' sceptre wherewith he chastises the boys by striking them on the palm of the hand.

The word is Latin, and has also been used to denote the prelate crozier and staff. It is supposed to be formed of the Latin, *ferris*, to *ferris*, or, perhaps, *ferula* in this sense may be derived from the name of a plant, called in Latin, *ferula*; in English, *fenugreek*; the stem whereof was anciently used to correct children with.

Under the eastern empire the *ferula* was the emperor's sceptre, as is seen on divers medals; it consists of a long stem or stalk, and a flat square head. The use of the *ferula* is very ancient among the Greeks, who used to call their princes *astrophaga*, q. d. *ferula eaters*.

In the ancient eastern church, *ferula* or *narthex* signified a place separated from the church; wherein the penitents or the catechumens of the second order, called *anastantes*, *anastantes*, were kept, as not being allowed to enter the church; whence the name of the place, the persons therein being, under penance or discipline: *sub ferula erat nathex*.

FERULA, in *Diction*. See *FERNET giant*.

FERULA, a word used by the ancients to express the horns growing on the deer or stag at the age of two years.

FERULA, among *Surgens*, called also *SPINTERS*, are little chips of different matter; as of wood, bark, leather, paper, &c. applied to bones that have been disjunct when they are set again.

The bark of the herb funnel giant, called by some in Latin, *ferula*, was anciently much used on this occasion; whence the name *ferula* became common to all.

FERULACOLI, in *Diction*, a name by which some authors have called the blafai, or triacle mastard.

FERULAGO. See *FERNET-giant*.

FERZAA, in *Natural History*, a name given by the Persians to that gent which we call the turquoise or Turkey-stone, a blue, opake, and soft gem. See *TOXICUS*.

FESCENNINE, in *Antiquity*, *Fescennine verses* were a kind of satirical verses, full of wanton and obscene expressions, sung or recited by the company, with many indecent jestures and dances, at the solemnization of a marriage among the Romans. Hor. ep. l. lib. v. 145.

The word is borrowed, according to Macrobius, from *fescina*, a charm; the people taking such songs to be proper to drive away witches, or prevent their effect; but its more probable origin is from Fescennium, a city of Campania, where such verses were first used.

FESOLI, or *FESOLI*, congregation. See *JEHOYIMITES*.

FESSE, in *Her-try*, one of the nine honourable ordinaries of the escutcheon, which it divides horizontally in the middle, and separates the chief from the point. It is supposed to represent a broad girdle or belt of honour, such as those with which knights at arms were anciently girded.

It possesses the centre of the escutcheon, and contains in breadth one third part thereof. Thus, he beareth azure, a *fesse*, or, by the name of Elliot. See *Tat. Herald. fig. 22*.

When the *fesse* takes up less than its proper breadth, it is called a *bar*.

FESSE-point is the exact centre of the escutcheon.

It is thus called, as being the point through which the *fesse* line is drawn from the two sides; and accordingly it divides the escutcheon into two equal parts when the escutcheon is parted *per fesse*.

FESSE-way, or *in FESSE*, denotes things borne after the manner of a *fesse*; i. e. in a line or range, across the middle of the shield, which the French call *en fesse*.

FESSE, *party per*, implies parted across the middle of the shield, from side to side, through the *fesse* point.

This the French express by one word, *espalé*.

FESSIER, in *Anatomy*, the name given by the French writers to what others call the glutens, or, according to Riolanus, the g'astrius. There are three muscles of this name among authors, the glutens major, medius, and minor, and the French call them the grand, moyen, and petit *fessier*.

FESTA, in *supra*, in *Middle Age Writers*, grand holidays, in which the whole choir of the cathedral were caps.

FESTI Dies, among the ancients, were *festi-days* or holidays.

Nomina distinguished the days of the year into *festi*, *profesti*, and *interfesti*. The first were those dedicated to the gods; the second were those allowed to men for the management of their own affairs; the third were shared between the gods and men.

The *festi dies*, again, were divided, according to Macrobius, Saturn. cap. 16, into *fortiores*, *opales*, or banquets; *ludi*, or games; and *feriae*; and the *profesti* into *festi*, *comitiales*, *imperiales*, *stati*, and *præstiales*.

FESTING MEN. See *FASTERMANS*.

FESTING-fenny, earnest given to servants when hired or retained. It is so called in some northern parts of England, from the Saxon, *fistian*, to *fist*, or *enfirm*.

FES LINO, in *Logic*, one of the moods of the second figure of syllogism.

In a syllogism in *festina*, the first proposition is a universal negative; the second, a particular affirmative; and the third, a particular negative.

FESTIVAL. See *FEAST* and *FESTUM*.

FESTOON, in a *General Sense*. See *GARLAND*.

FESTOON, in *Architecture* and *Sculpture*, is a decoration in form of a garland or cluster of flowers.

The word is French, *feslon*, which signifies a garland, formed of the Latin, *fessum*, *fess*.

It consists of a string or collar of flowers, fruits, and leaves, tied together, somewhat biggest in the middle, and suspended by the two extremes; from which, beside the main part which falls down in an arch, two lesser parts hang perpendicularly.

This ornament is made in imitation of the *fessum* or

long clusters of flowers, hung by the ancients on the doors of their temples, &c. on festival occasions.

Festum are now chiefly used in freestones, tablets, and other vacant places, required to be filled up and adorned.

They are sometimes used over and over a niche.

FESTUCA, *Festucaceae*, in the *Linnaean System of Botany*, the name of a kind of grass, which strikes a distinct genus of plants of the *tribus disticha* class; the characters of which are, that the calyx is a many-flowered glume, and is bristly, erect, and contains the flowers ranged together in a slender spike; the valves are straight, oblong, pointed, without awns, or beards, and the lower is the smaller; the flower is composed of two valves, the lower is the larger, this is of the shape of the cap, but it exceeds it in size, it is somewhat cylindrical and pointed, and is terminated by a straight beard or awn; the stamens are three capillary filaments, shorter than the flower; the anthers are oblong; the germen is of a turbinated form; the styles are two in number, and are short and bent backward; the ligaments are single; the flower closely surrounds the seed, which is single, oblong, slender, extremely sharp-pointed at each end, and marked with a longitudinal furrow.

FESTUM, in a *General Sense*. See **FESTAS**.

FESTUM, in out. *Law-terms*, is frequently used for a general court or assembly, because feasts were anciently always kept on the great festivals of the year.

Thus, in our chronicles, we read, that in such a year the king kept his *feast* at Winchester, &c. that is, he kept a court there at that time: *Rex apud Winton. maximum festum & convitium celebravit, tempore Natalis Domini, convocatis illius principibus & baronibus suis regi.*

FETCH *Way*, in *Navigation*, is to be shaken or agitated from one side to another. The terms are usually applied to a mast, bowsprit, &c. when it is not sufficiently bent, being loose in the partners, or to any body which is moved by the rocking of the ship, for want of being well secured.

FETCHING the Pump, is the act of pouring water into the upper part of it, to expel the air which is contained between the lower box or piston and the lower end of the pump that rests on the ship's floor; and accordingly to make the water poured into the chamber communicate with that in the bottom of the pump-well, so as to be thrown out above by striking with the break or handle.

FET-A, in *Modern History*, is a name which the Turks give to the written judgments or decisions of the mufti.

The word in the Turkish language signifies *fatwas*, and in Arabic, the *copy* or *judgments* of a *wise man*.

FETICHE, in *Modern History*, a name given in Guinea to their divinities; one of whom is supposed to preside over a whole province, and one over every family. This idol is a tree, the head of an ape, a bird, or any such thing, as their fancy suggests.

FET-Lock, in the *Mangee*, a tuft of hair growing behind the posterior-point of horses.

Hence, the joint where it grows is called the *fat-lock joint*.

FEUS. See **FORTUS**.

FEUD, *FEODUM*, the same with *fief* or *fee*.

Estates in land were originally at will, and then they were called *maneria*; afterward they were for life, and then they were called *beneficia*; and for that reason the livings of clergymen are so called at this day; and afterward they were made hereditary, when they were called *feuda*, and in our law *fee-simple*.

When Hugh Capet usurped the kingdom of France, about the year 947, to support himself in such usurpation, he granted to the nobility and gentry, that whereas till then they generally enjoyed their honours for life, or at will only, they should from thenceforth hold them to them and their heirs. However, under the reign of Ludovicus Pius, who succeeded his father A. D. 814, grants of hereditary fiefs were frequent in France. Muratori observes, that the word *feudum*, which came to be substituted in the place of *beneficium*, does not occur in any authentic charter previous to the eleventh century; and Dr. Robertson adds, that a charter of king Robert of France, A. D. 1008, is the earliest deed in which he has met with the word *feudum*. Hist. Ch. V. vol. i. p. 269. This was imitated by William, called the Conqueror, upon his accession to the crown of England; for till his reign *feuds* or *fees* were not hereditary, but only for life, or for some determinate time. See **FIE**.

Feuds were by various names, according to their respective natures; as *feudum antiquum*, which descended to a son, &c. from his ancestors; *apertum*, resuming back again to the lord of the fee, where the blood of the last person last seized in fee-simple is utterly extinct and gone; *honorarium* and *indivisum*, a title of nobility, not

of a divisible nature, and descendible to the eldest son in exclusion of all the rest; *improprium*, an improper or derivative *feud*; *matrimonium*, descending to the son from the mother; *meum*, one newly acquired by the son, to which, in ancient times, only the descendants from his body could succeed, by the known maxim of the early feudal constitution; *novum*, held at *antiquum*, descendible in the same manner as a *feudum novum*; *patrimonium*, descendible from father to son; and *proprium*, a proper *feud*, distinguished from one improper, which are the two grand and general divisions. Blackst. Com. vol. ii. *Feud* is also used in our ancient customs for a capital quarrel or enmity, nor to be satisfied but with the death of the enemy; and thence usually called *deadly feud*.

Feud, called also *feide*, and *feide*, in the original German signifies *guerram*; i. e. *bellum*, war. Lambert writes it *feith*, and faith it signifies *capitalis inimizia*, or implacable hatred.

In Scotland and the North of England, *feud* is particularly used for a combination of kindred, to revenge the death of any of their blood, against the killer and all his race, or any other great enemy.

FEUDAL, or **FEODAL**, or, of belonging to a *feud* or *fee*. See *law*, a *feudal* matter, *feudal* jurisprudence, *feudal* tenure, &c. A *feudal* lord, in default of fealty and homage from his vassal, may seize the fruits of the fee. A Neapolitan lawyer, called Carvina, has a Latin treatise of the *feudal* law, intitled, *Prælectiones Feodales*.

When once the use of fees was thoroughly established in France, they would needs extend it much farther, and almost all the great offices of the crown thus became *feudal*; even the courts of justice were drawn in, in order to which, they were annexed to certain lands or revenues.

The design of these intoductions was to render the offices hereditary, after the manner of fees, which were now become so; and thus the offices of the grand chamberlain, grand butler, &c. came to be held by hereditary right.

As the Northern nations brought in the use of coats of arms, by preferring down in their families the armorial bearings of their ancestors, shields, &c. as hereditary marks of honour, so they also, according to some, brought in the *feudal* law, by means of which arms grew up to *feudal* perdition, as is evident by many armorial figures of ancient families, representing the acknowledgments and services they were obliged to perform to their own lords and superiors.

Thus, roses, cinquefoils, spurs, bows, bow and arrows, hunting horns, ships, and the like figures, were expressive of the services they were bound to do their lord; and hence these figures have become common in arms throughout all Europe. For instance, the old barons of Arran and Lorn were obliged to furnish their lord with a ship in time of war; and thence it is that their arms carry ships or lymphods to this time.

FEUDATARY, or **FEODATARY**, a vassal or person who holds of a superior in fee: i. e. on condition of yielding him fealty and homage, or other service. See **VASSAL**. The electors, princes, and free cities, of Germany, are all *feudataries* of the emperor.

FEUDBOTIE, a recompence for engaging in a *feud* or action and for the damages consequent thereon; it having been the custom of ancient times for all the kindred to engage in their kinsmen's quarrels; according to that of Tacitus De Morib. Germanor. *Supplicium tam inimizias seu patrii, seu propinqui, quam amicis, necesse est*.

FEU de jour, in the *Military Art*. See **Running FIRE**.

FEUDIST, a lawyer, or doctor learned, or much conversant in feuds or fees. Du-Moulin is reckoned a great *feudist*.

FEVE. See **AURELIA**.

FEVER, **FEBRIS**, in *Medicine*, a *disease*, or rather class of diseases, whose characteristic is a preternatural heat felt through the whole body, or, at least, the principal parts thereof, attended with other symptoms.

Sydenham defines a *fever*, a strenuous endeavour or effort of nature to throw off some extraneous matter that greatly incommodes the body. Quincy defines it, an augmented velocity of the blood, others, a fermentation of the blood, accompanied with a quick pulse and excessive heat.

Fever are of various kinds, denominated and distinguished from the particular causes that produce them; the time they continue; their access and returns, and their different symptoms.

Riverius reckons above thirty different kinds of *fevers*; and Sydenham has increased them to double that number; but certainly physicians have observed something common to all these diseases, which made them denominate them *fevers*. A late author thinks, that the consideration of what constitutes a *fever*, which he thinks

very simple and obvious, with its true causes and genuine effects, will give a more just and clear notion of the disease, and lead to a more rational practice than all that has been said by authors at so great length on these false and unnecessary distinctions. He thinks the most natural and useful division of *fevers* is into continued and interrupted; and he conceives they may all, when considered simply, and not as the effect of another disease, be reduced to one or other of these two sorts. *Medic. Ess. Edinb.* vol. 1. p. 264, 265.

In every *fever* from an internal cause, the three chief observables are these: first, an universal trembling, and then an increased heat and quick pulse: a *fever* almost always begins with a cold or shivering; and soon after, the pulse growing quicker, affords the primary diagnostic of a *fever*. The health of the patient seems to be the primary aim of nature in *fevers*, though they often terminate in death.

By Dr. Brown Lough's static experiments made on the blood of people in acute continued *fevers*, compared with what he says of the blood of three young men in perfect health, it appears, that in *fevers* the serum is in less proportion, and the crystallinum is more viscid and tenacious than in health. The indications of cure from which are plain. See his *Modern Theory and Pract. of Phys.* p. 68, 74.

By the chemical analysis it is proved, that in acute *fevers* the saline and sulphureous parts abound more than in health; and that the urine is impregnated more and more with these saline and sulphureous principles, as the symptoms abate upon a crisis by urine.

FEVERS, *fever* of. There are an accelerated progressive motion of the blood, distinguished by the quickness of the pulse; this is succeeded by an increased heat in the body, and immediately after this the tonic motion of the parts is either constricted or relaxed. This is first in the face: in the first case, it becomes red and bloated; in the latter thin and pale: these symptoms are succeeded by an immoderate thirst, and a loathing of food of all kinds; an absence of sleep, or disturbed and unrefreshing sleep; and a pessimism or uneasiness in the temper, with an extreme sensibility of every thing, and a neglect of the common business of life: after this there is a great loss of strength, and an insupportable anxiety; a sensation of pain in some parts; a very uneasy and difficult respiration; a sweating more than usual; and finally, there is a change in the urine, in colour being usually very high, and its consistence thicker than that of persons in health. When the *fever* comes on gradually, the patient generally complains first of languor, listlessness, soreness of the feet, or of the bones, as it is vulgarly expressed; brachia of the head, loss of appetite, sickness, with clamorous of the mouth; after time these succeed excessive heat, violent thirst, inability to sleep, &c. When the *fever* attacks suddenly, it always begins with an uneasy sensation of excessive cold, accompanied with debility and loss of appetite; the cold is frequently attended with shivering, oppression about the heart, and sickness of stomach, or vomiting. Boelha.

FEVERS, *general cause* of. These are an overheating the blood by exercise, and thus throwing it into violent commotions; violent and sudden cooling of the body when very hot; the abuse of spirituous liquors, and the eating large quantities of foods hard of digestion; a watchfulness beyond the usual custom, such as long sitting up by the sick, or the like; and the suppression of any accustomed evacuation, particularly of habitual hemorrhages by the nose or other parts. Besides these, the passions of the mind very frequently throw people into *fevers*; and it is observed also, that persons often accustomed to have *fevers* are much more easily thrown into them on slight accidents than any others. In all these causes are to be added those of contagion, unwholesome air, and external or internal injuries.

FEVERS, *prognosis* in. All *fevers* are in their nature salutary, being the means nature uses to rid herself of something that oppresses her, yet they are often fatal to the event; but this is rather to be attributed to the fault of the constitution than of the *fever*. The cause of the disease being impeded, and other diseases coming on, the patient often dies under them; so that the most judicious physicians observe, that people rather die with a *fever* than of a *fever* in these cases.

It is to be observed in general, that of the great number of persons who have *fevers*, very few proportionably die of them.

Fevers very often are cured by nature alone, and go off very happily only by the patient's abstinence, a quiet state, and keeping up the natural evacuations. In this manner great numbers recover without the help of medicines; a number almost as great is destroyed by medi-

cines, which, when administered by persons who have not sufficient judgment, interrupt nature, and prevent the necessary excretion. *Fevers* go off, according to the language of physicians, either by a crisis or lysis: in the first case, they leave the patient at once, after the critical days; in the other, they wear off gradually, growing slowly less and less violent. The acute *fever* usually goes off in the first way; the intermittents in the other. Critical evacuations, of whatever kind, when they happen in sufficient quantity, bring with them a sort of instantaneous cure, the patient becoming well and easy from them, though immediately before he was in the utmost anxiety and uneasiness. No *fever* ever goes off without sweating, and a change in the urine. But in *fevers*, in general the sweats do not come on at first, but afterwards; and in general, the sweats never come on during the violence of the burning heat, but when that remits a little, the sweat breaks out. If it appears during the excessive heat, the prognosis is bad, at least, it is of no use or good to the patient. Sweats coming on at a proper time, and flowing in a proper degree, bring on recovery; but when they are suppressed, the disease becomes worse; there is pain and languor in the limbs, and the disease is protracted in length, and from an acute, becomes a slow *fever*. It also seems to be no change perceived in the urine, and the heat do not exceed the ordinary standard, it is a fatal prognostic for the patient; and the old physical axiom is usually verified, that while the pulse and the urine are well in *fevers*, the patient dies.

A defection of spirits in a *fever*, and a melancholy state coming upon a person usually cheerful when well, is always a bad omen.

The several different kinds of *fevers* have their stated times in which each attacks the patient. Tertians usually seize people about dinner-time, and are particularly common about the period of the vernal equinox. Quartans usually make their first attack about four or five o'clock in the afternoon, and are more common in autumn than at any other season of the year. The typhocha, or continent *fever*, expressly so called, usually attacks persons in the morning before day-break. Billious *fevers* usually make their first attacks about the time of sun rise, and are most common in the middle of summer. The catarrhal *fevers*, finally, most commonly attack persons in the evening, and they are most frequent about the equinoxes. The more any *fever* departs from its usual course, the worse is the prognosis; any *fever*, when it has been improperly treated by medicines, becomes much more stubborn and difficult of cure than when it has been left to itself. The particular medicines which disturb the course of nature in *fevers*, and by that means render them more difficult of cure, are abstersives, too powerful absorbents, opiates, &c. And it is observed, that when *fevers* go off happily and easily, especially when they go off of themselves without medicines, the patient always enjoys a better state of health after than he had before. *Juncker's Comp. Med.* 257.

FEVERS, *method of cure* in. The physician in all *fevers*, is to endeavour to make himself the servant and assistant of nature; what nature endeavours in the beginning and increase of the disease, is to prepare, dispose, and search the noxious matter; and in the state and decline of it, to eliminate and evacuate the matter so prepared by the proper passages. The whole business of art is, therefore, to assist nature in these two efforts of secretion and excretion of the matter.

The method of doing this in every particular species of *fever*, is to be seen under their several particular heads; but as we are here treating of *fevers* in general, it may be proper to give the method of treating them as *fevers*, without running into the several sub-distinctions.

The remedies which we are to give to assist the secretion and preparation of the noxious matter, are the diluting and cooling liquors in general: such are a sufficient quantity of warm and weak fluids, as the common barley-water, and the like; and teas made of the common herbs of sage, mint, balm, &c. with the milder alexipharmic roots. Nothing is more likely to abate the heat, attenuate the humours, remove spasm and obstructions, promote perspiration, increase the quantity of urine, &c. in short, produce every salutary effect in an ardent or inflammatory *fever*, than drinking plentifully of water, thin gruel, or any other weak diluting liquor; of which water is the basis: the necessity of such liquors is plainly indicated by the dry tongue, the parched skin, and the burning heat, as well as by the thirst of the patient. Many cooling liquors, very agreeable to patients in *fevers*, may be prepared from fruits, as decoctions of tamarinds, apple-tree, orange-juice, &c. with these also are to be given the gentle relaxants, such as are able to break the thick and tough confluence of the humours. Of this kind are the temperate alexipharmic roots especially;

cially, as they are also endowed with a diuretic virtue. Such are the roots of elecampane, pimpernel, butterbur, and the like. Scordium is also by some greatly recommended in this intention. These may be conveniently given in decoctions or infusions; and with these powders are to be given, composed of the absterive and digestive salts, such as tartarum vitriolatum, and the like, mixed with such things as have a power of obtonding and increasing the acid and thin sulphurous saline humours; such are the absorbent powders of oxytelles, crab's-claws, and the like. These should be first fused with lemon juice, and then mixed with a little nitre, and with the before mentioned salt, they make an excellent medicine. They may be given every three, four, or six hours, as the urgency of symptoms requires, and a draught of the decoction before prescribed given after them. The absorbent powders have been commonly prescribed in *fevers*; but it would be better if they were neglected. Emulsions of sweet almonds, and the cooling feeds, are also very proper at convenient intervals. See FEVERIFUGES.

The method of suppressing *fevers* by means of cold, now commonly adopted, was practised by Hippocrates, Galen, Celsus, Avicenna, and the ancients who exposed their patients to cold air, and they gave them cold water to drink. Nothing is more desired by a patient in a *fever* than fresh air; it removes his anxiety, cools the blood, revives the spirits, and is in every view beneficial. There ought, therefore, to be a constant stream of fresh air in his chamber, so as to keep it moderately cool. Air that has been repeatedly breathed, when the blood is inflamed, or the humours are in a putrid state, becomes unfit for respiration, and acquires a noxious quality. See AIR, fresh, and Blood.

The medicines by which the physician is to assist nature in her following business of excretion, are the gentle diaphoretics, among which the diaphoretic antimony, when truly prepared, holds a very high place. The alexapharmics, which have also a diuretic virtue, such as the mixture simplex, when faithfully prepared and lightly camphorated, are very proper; and the bowels are in the mean time to be kept open by emollient clysters. These things are proper in all *fevers*; but in some, also vomits, gently laxative medicines, and bleeding, are extremely proper: these, however, are not to be admitted at random in all kinds.

At the beginning of a *fever*, the patient generally complains of great lassitude or heaviness; and this symptom evinces the propriety of keeping him easy, and, if possible, in bed: lying in bed relaxes the spasms, abates the violence of the circulation, and gives nature an opportunity of exerting all her force to overcome the disease. The bed alone has often removed an incipient *fever*. The food of the patient in a *fever* should be light, and easy of digestion, and given in small quantities: it ought chiefly to be of the vegetable kind, as panna, roasted apples, gruel, and such like. All violent medicines are to be avoided in *fevers*; for nature usually attempts to do her office placidly and quietly in these cases, and such medicines violently disturb her motions, and often bring on mischief which the would have wholly avoided. For this reason, vomits, though they are by some given indiscriminately in all *fevers*, are to be very cautiously meddled with; and there are, in reality, only a few *fevers* in which they can be allowed to be proper; for in acute legitimate *fevers*, the cause of the disease never lies in the prime viæ; and the violent emotions in vomiting not only distressfully disturb the stomach and bowels, but occasion a salivosity of the vessels about the head and neck, with various disorders of the head in particular. In bilious *fevers*, the cause is indeed evidently in the prime viæ; but even in these, it is not to be disposed of to be so safely thrown up by vomit, nor can the inflammatory state of the patient at that time properly bear such a violent shock. In intermittents, vomits are never proper, unless in tertians, for the cause in the other does not lie in the prime viæ; and even in tertians, it may be disposed to evacuation by proper means, and without the violent tumult that a vomit occasions in the body. Notwithstanding the cautions above given with respect to the use of vomits, they are in many cases very necessary and beneficial on the first attack of a *fever*. Antimonial medicines, administered for this purpose, curb the circulation, and promote all to be discharged. Their influence on the whole nervous system is such, that the strength is rarely so much reduced when they are duly adverted to as when they are omitted.

Acid purges are in general to be avoided in *fevers*. The proper medicines of this kind are the sal Glauber. var. tart. vitr. sal polybreit. or Ruppelsen's, tamarind, rhubarb, and manna; and if two or three grains of the emetic tartar is added in cases that indicate a vomit to be

proper, they will operate both ways, and there will be no occasion for administering an emetic by itself. Bleeding, though absolutely necessary in synchral or continous *fevers*, is not advisable in many others; and very often the opening of a vein, and taking away too little blood, is the occasion of congestions of blood in the head, whence arise delirium and other dreadful symptoms. The state of dietetics in this country is so much altered, that true inflammatory *fevers* are very rare; and that there is hardly one *fever* in ten where the lancet is necessary. In many cases bleeding would be very prejudicial; and this general rule may be observed, never to bleed at the beginning of a *fever*, unless there be evident signs of inflammation. The giving of hot sudorific medicines before the proper time greatly disturbs nature, and brings on many ill consequences. Junker's Consp. Med. p. 261. Buchan's Med. chap. 12.

In all *fevers* the drinking plentifully of warm and cold weak liquors is attended with many good consequences; the patient is always refreshed by it, the febrile heat is mitigated, rest is promoted, and the proper and necessary sweats forwarded. The symptoms of *fevers* are never to be regarded as to prevent the due attention to the principal point, and is the physician to be alarmed at them. Want of appetite, and thirst, with long watchings, are not to be attacked with particular medicines, but looked upon as mere symptoms that will hereafter go off of themselves; and inquiries of mind should have no other medicine than serious advice of the harm it will do. Sudden cooling of the body in all *fevers* is a very dangerous thing. The patient is advised to swallow his liquids gently, not hastily. Volatile salts have been with many of a long time in great use in *fevers*; but they are usually attended with bad consequences afterwards, many persons having been thrown into dangerous swellings of the legs and feet, and some into an absolute apoplexy, only by the use of these in *fevers*.

Acids in general are by many very much dreaded in *fevers*; but there is no real ground for this: on the contrary, in sanguineous *fevers*, during the time of the violent heat and immoderate thirst, they are found of the greatest use and benefit. Spirit of vitriol, or of sulphur, lemon-juice, with that of barberries, are all found very beneficial; only in cases where there is a cough, the vitriolic acid is to be avoided, because it usually irritates that symptom, and lemon-juice sweetened with sugar alone is to be given. The use of astringent medicines, though too common, yet is extremely improper in all *fevers*; for in all these cases the secretions and excretions all require to find the ways open; but these are all obstructed by astringents, and violent symptoms are brought on by this means, and often death. But in stubborn intermittents, where the peccant matter is discharged, and yet these symptoms remain merely from their having become habitual, these astringents may be allowed of, and are indeed not only safe, but of the greatest use. Junker's Consp. Med. p. 263.

Nitre is an admirable medicine in *fevers* in general; it agrees with all temperaments, but principally with the hot, when taken in solution with warm and weak liquors, it always gently opens the bowels; and when given in powders, it more than all other things obtains the acrimony of the humours.

In febrile disorders, accompanied with hemorrhages, the arnica vera has been recommended. See ARNICA vera.

The most general and genuine division of *fevers* is into *essential* and *symptomatic*.

Essential fevers, is that whose primary cause is in the blood itself, and which does not arise as an effect or symptom from any other disease in the solids or other parts.

This is what we absolutely and properly call a *fever*.

Fevers, symptomatic, is that which arises as an accident or symptom of some other antecedent disorder; as an inflammation, phlegmon, erysipelas, impoethum, smallpox, pleurisy, &c.

Whence it is peculiarly denominated inflammatory, erysipellous, parulent, variolous, or pleuritic *fever*.

Essential fevers are generally distinguished into *continued* and *intermittent*; others choose to divide them into *diary*, *intermittent*, *continued*, and *continued*.

Fevers, continued, is that which gives the patient no respite or intermission, or which shows no remarkable increase or abatement in the symptoms.

This is subdivided by some into the *acute*, *ardent*, or *inflammatory*, the progress of which is quick, and the symptoms violent; the *slow* or *nervous*, in which these are more gentle; and the *malignant*, *putrid*, or *petenial*, when livid or petenial spots manifest a putrid state of the humours; and by others into *putrid* and *not putrid*.

Fevers not putrid, continued, is that wherein the parts of the blood are not so dissolved and broken as to give occasion

for the principal parts thereof to be secreted; or that wherein there is not any discharge of purid, purulent matter into the blood.

Fever, continued purid, is that wherein the texture of the blood is rendered to lax, or even dissolved, that its parts be principally separating, some of the principal of them are secreted and lost. See *Purid Fever*.

Fever, ardent or inflammatory, called by the Greeks *pyrexia*, is a very acute fever, generally introduced by rigor or chilliness, and attended with a vehement heat, a frequent and full pulse, a pain of the head, dry skin, redness of the eyes, a hard countenance, pain in the back, loins, &c. difficulty of breathing, dry coughs, extreme thirst, restlessness, and commonly a rough and black tongue. The more dangerous symptoms are a delirium, laborious respiration, flaring of the tendons, hiccup, cold clammy sweat, and an involuntary discharge of urine. The patient is most subject to this fever at the young and vigorous, and plethoric, and it is most frequent in the spring and beginning of summer. It is occasioned by violent exercise, strong liquors, and a full diet with little exercise, and by any thing that obstructs perspiration, as lying in the damp ground, drinking cold liquor when the body is hot, watching, &c. This fever seems to have no critical time for its termination, either in recovery or in death. When it is very violent, or very badly conducted, it sometimes proves fatal on the ninth day. *Peccans* often die from the eighteenth to the twentieth; and sometimes about the fortieth day, after having been alternately better and worse. The general course of this fever is determinable from the fourteenth to the thirtieth day. The regimen proper for this fever should be such as is calculated to disperse the blood, correct the acrimony of the humours, stay the excessive heat, remove the palmonic fluidure of the vessels, and promote the secretions. The patient should, therefore, drink plentifully of diluting liquor, as water-crud, clear whey, barley-water, bannetia, &c. which may be sharpened by juice of orange, curcullin jelly, &c. or a decoction made by boiling in milk and water a bitter orange, sliced, or a lemon, a little cream of tartar, or a few spoonfuls of vinegar, till the curd separates, is an excellent cooling drink. Two or three spoonfuls of white wine may be added to the boiling liquor. If the patient be colic, an ounce of tamarind, with two ounces of flowered rafins of the sun, and a couple of figs, may be boiled in three pints of water to aquat, and this liquor may be used or decoction. His diet should be spare and light, and consist chiefly of gruel, panada, roasted apples, &c. He should be relieved by the admission of fresh air into his chamber, and by sprinkling it with vinegar, lemon-juice, or vinegar and rose water, with a little nitre dissolved in it. His mouth should be often washed with a mixture of water, honey, and vinegar; and his feet and hands should be frequently bathed in lukewarm water, especially if the head be affected. To which we may add, that the patient should be kept as still and composed as possible. Bleeding should be performed as soon as the symptoms of an inflammatory fever appear, and repeated at the distance of twelve, eighteen, or twenty-four hours, according to the symptoms, till the humors, and fulness of the pulse are sensibly altered. Hemorrhages, or bleedings from the nose, often occur in this fever, much to the relief and security of the patient. If the fever and heat be very great, forty or fifty drops of dulcified spirit of vitriol may be made into a draught, with an ounce of rose-water, two ounces of common water, and half an ounce of simple syrup; and this draught may be administered every three or four hours while the fever is violent. When the patient discovers an inclination to vomit, the efforts of nature should be assisted by weak chamædorea-tea or lukewarm water. If the belly be bound, a clyster of milk and water, with a little salt, and a spoonful of sweet-oil or fresh butter in it, should be daily administered; and if this should fail, a tea-spoonful of magnesia alba, or cream of tartar, may be frequently added to the patient's drink. If about the tenth, eleventh, or twelfth day, the pulse becomes more soft, the tongue moister, and the urine begins to deposit a earthy sediment, the disease promises a favourable issue; but if, on the contrary, the spirits of the patient become languid, the pulse sinks and yet retains its hardness, and his breathing becomes difficult, accompanied with a stupor, trembling of the nerves, flaring of the tendons, a swelling of the belly, wildness of the eyes, and constant rage, there is great danger. In this case blistering-plasters should be applied to the head, ancles, inside of the legs and thighs; and poultices of wheat-bread, mustard, and vinegar, may be likewise applied to the soles of the feet; and the patient should be supported with coffee, as white whey, negus, fag-gruel with wine in it, &c. As this disease is always

attended with danger, the best medical advice should be procured as soon as possible.

Inflammatory fevers may be distinguished into two stages; the first, while the pulse continues hard, in which it is proper to bleed; and the second, when the inflammatory symptoms still remaining, the pulse is the low for that evacuation. In this last state, blisters are the chief remedy, and which, except in a few singular cases, are not to be used sooner. If the blisters are larger it is better to apply them gradually, than many at a time. It is usual to begin with the back, and, if necessary, to apply them next to the legs or the thighs, referring the arms last; that the patient may be so much the longer conveniently moved. There is no caution more necessary to a young physician, than to abstain from all opiates through these fevers, however much the patient may complain of pain or watchfulness. Indeed, if the fever be accompanied with a diarrhoea, which is not critical, the blood-letting is to be gradually checked by discharges, after giving rhubarb, and endeavouring to turn the humours to the skin by the use of the diaphoretic, omitting the fire, with the use of the viscus siccation for the common drink. When the patient is beginning to recover, he should avoid excess of food, drink, exercise, and company, for fear of a relapse, and if his digestion be bad, and he should be troubled with feverish heats, an infusion of Peruvian bark in cold water will be of use; and when he has recovered his strength, he ought to take some gentle laxative. *Buchan's Dom. Med. chap. 15, and Tillo's Adv., &c. p. 244, &c. Pingle's Obs. on the Diseases of the Army, p. 134, 135.*

To the class of *burning fevers* are reducible the *typhus*, *phlogia*, *bilious*, &c.

The *typhus* is a *burning fever*, wherein the heat is very intense within-side, and at the same time the external parts are cold.

The *phlogia* is a *burning fever*, attended with great inquietudes, noisiness, vomiting, &c.

The *bilious* is a *fever* wherein the patient sweats continually.

The *phlogia* is that attended with frequent froonings.

The *typhus* is that wherein both heat and cold are felt in the same part at the same time.

Fever, bilious. When a fever is accompanied with bilious discharges by vomit or stool, whether it be continual, intermitting, or remitting, it is called bilious, and belongs to the class of *ardent fevers*. See *Bilious fever*, and *Choleric fever*.

Dr. Ferrius, in his *Essays Medical and Experimental*, informs us, that in these fevers the powder of columb root, given in doses of fifteen to twenty grains, with vitriolated tartar, from one to two scruples every four, five, or six hours, produces both speedy and beneficial effects. Dr. Hagarth of Chester farther remarks, that after the prime via are unloaded of their bilious contents, the vomit becomes admixt, his always the nausea, constantly attendant on this disorder, and that it answers our warmest wishes, by correcting the bile, restoring the proper tone of the stomach, and of the whole habit; and that it is an excellent preventative of relapses to which patients in this disorder are peculiarly disposed.

Burned fevers, of the West Indies, called also the *yellow fever*, frequently attacks the Europeans, who indulge in excess, and are not careful to guard against the heats and dews that are common in that part of the world. It attacks with a transient chilliness and shivering, which are soon succeeded by a burning heat all over the body, and more particularly about the præcordia; the pulse is high and quick, but not hard; the eyes are heavy; a violent head-ach follows, with a strong pulsation of the temporal arteries, and a laborious respiration; a insula succeeds with bilious discharges; the anxiety of the patient is very great, and he feels pain in the back and loins, and an uneasy lassitude in the limbs. In about twelve hours after the first attack, the tongue is very dry, rough, and discoloured; the thirst is excessive, a forecels is felt all over the body, and a delirium comes on. In the last stage the patient labours under a coma, manifests great oppression about the præcordia; at length the tendons tremble, and cold sweats and convulsions terminate in death. When the patient recovers, the crisis usually happens on the fourth day after the attack, and discovers itself by a fullness of bile all over the body, and a yellow tinge in the eyes is reckoned a favourable prognostic. Incontinent vomiting, with discharges growing of a darker colour, is a fatal sign; and if a dry skin, which is a threatening symptom, accompanies in inflamed respects of the eyes, death may be expected in a few hours. Bleeding should be immediately proposed; but after the third day it is hardly advisable. Then one or two grains of tartar emetic should be given for evacuating

ating the bile; and the belly must be kept soluble by repeated doses of saline purges. When the prime vis is evacuated, the bark, either in substance or infused in cold water, must be freely used, in doses as large and as often repeated as the stomach can digest them. It should be given as soon as a remission is observed, or a diaphoresis produced. The columbo-root should be also tried. Bladders may keep off the coma, or if it comes on, they should be applied to the head, arms, and legs, and sinapisms to the soles of the feet. Cordial medicines, with camphor, should be also duly administered. Motherby's Dict.

Fever, benign catarrhal, in Medicine, the name given by authors to a *fever* extremely different from the malignant one of the same denomination, which is also called by way of distinction, *petechial*. This is the disease described in the writings of the ancients, under the name of *febris quotidian continua*. It is properly a continual symptomatic fever, in which nature is labouring of herself to correct the vitiated lymph, whether its fault be in quality or only in motion. This is done by increasing the secretory or excretory motions beyond their natural standard, but yet not to any great violence. The difference between this and the malignant kind, though it is very great as to make them appear wholly different species, yet is only in degree. Junker's Conspectus Med. p. 313.

Signs of it. This *fever* always attacks people in an evening, and is principally frequent in the spring and autumnal seasons. It proceeds and ceases either *per se*, or is immediately joined with it, and the patient is afflicted with a heatiness and difficulty of swallowing, he feels also a kind of inflammation, or, as it were, St. Anthony's fire within his throat, and a weight in the breast; it is attended through the whole course of the disease with a violent cough, which brings up nothing, and with a remarkable universal languor of the body. Pains in the back, attended with shiverings, frequently also attend the first attacks of this *fever*, and continue half an hour, sometimes an hour; these are succeeded immediately by a gentle heat, and this brings on a sense of thirst over the breast, a difficulty of breathing, and in some people a continual reaching to vomit. This heat endures fewer or more hours, according to the degree of the plethora. The pulse is frequent and quick, the appetite is weak, the strength fails, and the sleep becomes uneasy and disturbed; the head rather feels weak than painful; and sometimes vomitings, often diarrhoeas, run successively complaints. Sweats are frequent and copious; and the urine, which is of an orange-colour, as it is in all inflammatory fevers, has this peculiar quality in this case, that it deposits a bluish white skin, beside the rose-coloured sediment.

Persons subject to it. These are principally those of a sanguine or phlegmatic habit, and such as have a very florid countenance; such as are afflicted by their usual occupations to expose their head and neck much to the cold; those who have had the itch, or any other violent cutaneous eruption break in upon them; and those who are watchful long in the night, and drink too much wine.

Cures of it. These are frequently violent and sudden cooling of the body, as when hot with exercise, by drinking large draughts of cold liquors; the acid matter used to be thrown off by a coriza, driven back; and all things which any way impede natural and healthful perspiration.

Precautions of it. The simple catarrhal *fever* often goes off very happily without the assistance of medicines, only by observing a good regimen; but notwithstanding this natural mildness, it often becomes dangerous to particular constitutions, and by means of improper treatment; but the more it recedes from its natural mildness, and the more intense the heat is, the greater fear there is of some of the viscera being injured. The happiest event of it is by a daily resolution and successive dissipation of the morbid matter.

Method of treatment. The task of the lymph in this disease, usually confining in its viscous and mucous textures, is to be relieved by alexipharmics, and the like medicines. The roots of elecampane, pimpernel, and vinetoxicum, are famous for doing great service in these cases; and to these may very properly be added the saline diaphoretics, such as nitre, and the tartarum vitriolicum. The mixture simplex is also to be given in doses of twenty-five drops, twice, or oftener in a day. The cough is to be moderated by liquorice, emulsions of sweet almonds, oil of almonds and barley-water, water-gruel, or the like. The bowels are also to be gently kept open by a laxative diet, a frequent drinking of weak and cooling liquors, and by clysters at proper times. See CATARRH.

Fever, malignant catarrhal, in Medicine, the name of a *fever* extremely different from the simple catarrhal *fever*,

and much more dangerous. This is also called by some the *petechial catarrhal fever*. It is a disease in which nature is endeavouring, by increasing the secretory and excretory motions, to eliminate the catarrhal, viscid, and active matter. This is unquestionably the same species of *fever* with the simple one of this name, but extremely different in degree, and is often even epidemic. This is called by some the *febris Hungarica*, and *febris infectio contagiosa*; but the latter appellation is not to expect it in its very worst state, and when attended with its most terrible symptoms. The peteching, or spots, in this *fever*, are to be carefully distinguished from those in the common febrile cases. Junker's Conspectus Med. p. 317.

Signs of it. These are the same with those of the simple catarrhal *fever*; but with this difference, that in this case there are also violent anxieties of the mind, a sudden relaxation of the strength, a continual difficulty of breathing, and a loathing of all kinds of food. This last symptom usually continues till the eleventh day. The patients are also subject to frequent faintings, and are usually delirious, and complain of very sharp pains in the back, and at the joints. After these symptoms the petechiae usually appear; they are at first red spots on the breast, &c. resembling flea-bites. When low medicines are given, the petechiae are enlarged. Aphae and quinagies are also very frequent auxiliants on this *fever*, and diarrhoea seldom fails of appearing at some stage of the disease, and are often critical.

This *fever* seldom attacks the patient with a shivering. It is very contagious, in the manner of other malignant fevers, and has this peculiar circumstance, that it is very often complicated with other diseases; and, according to the seasons and other accidents, frequently appears under their form. In February, March, and April, it often has the appearance of a pleurisy; in May, and June, it often affects the symptoms of the *chaussée febris*; and at this season of the year is frequently, in the begining, attended with terrible hemorrhages. In July and August, a dysentery is frequently joined with it; and in the winter months, it generally has a badness attending on it. Persons of tender habits are much more subject to this disease from infection than those who are of a hardy and robust make. But as it is contagious, it sometimes passes no age, sex, or constitution, that come in the way.

Cause of it. The most frequent causes of this disease are a fermentaceous and purid exhalation in the air, and the contagion from the bodies and effluvia of the sick; and in the last case, a mortal terror of receiving the infection is often found to make people more susceptible than ordinary to receive it. And to these are to be added the eating of vitiated and fermenting provisions, and the sudden cooling of the body when very hot with labour or exercise, and frequent and violent passion, &c.

The spots which appear on certain days in this disease are not essential to it, though common; and hence the *fever* is rather called by accurate writers, *febris contagiosa*, than *petechialis*; they are a relief to the patient, if they are not violently repelled, or some other way improperly treated. When they appear earlier than the seventh day, they are also observed to be worse prognostics than when they appear on, or after it. When the spots appear in very great numbers, they usually fly back again, and the patient is much endangered by it. And when they are of a bright red, and after three or four days appear once go off again, and leave the patient better than before, they are a sure good prognostic. But if they be of a livid or black colour, they are a very bad omen; and when after the eruption the patient does not find himself relieved, the consequence is often a military purple *fever*. Lightheadedness before the seventh day is less dangerous than it does not happen till after it. Diarrhoeas in all other eruptive fevers are a very bad symptom, and often preface the death of the patient. But that is not the case in this; they sometimes prove critical, and carry off the disease. But when that is not the case, they are of no bad effect, and are always better for the patient than an obstinate constipation. But it is to be observed, that though these diarrhoeas, when they come naturally, are of great relief in many cases, and of no harm in others; yet still it is not here to be used as nature, and no purging medicines are by any means to be given to bring on a laxity of the bowels.

Method of cure. Gentle evacuations are to be brought on by such medicines as encourage perspiration, and promote urine. Abstersives, saturated with acids, as crab-apples, faced with lemon-jelly, are of service; and to these should be joined a small quantity of nitre. Cooling emulsions are also to be given at times; and spirit of nitre, camphorated, is to be rubbed on the head to mitigate the violent head-ache. And small gently recommended.

recommends, in the case of a too violent diarrhoea, the use of powder made of purified nitre, and mountain crystal. In cases of obstinate colic, cathartics must be injected as often as is found necessary; and when there is a complaint of flatulency in the faeces, and difficulty of swallowing, alluring gargles are to be used. *Junker's Comp. Med. p. 322.* See *Hospital fever*, and *Pseudo-fever*.

FEVER, choleric. In *Medicine*, the name of a fever, called also by some *bilious fever*, and by others a *catarrh*; though the generality of writers distinguish the *choleric fever* from the *catarrh*. All bilious fevers are properly species of acute fevers, and owe their origin to different degrees of the bile, at times when the elements are in a state of fermentation in the stomach and intestines.

The *catarrh* is distinguished from the *choleric fever* properly so called, by its being ever much more violent and dangerous, and by the exertions which attend it. For in the *choleric fever* the vitiated gall and other bilious excretions are always plentifully voided, sometimes upwards, sometimes downwards, and sometimes both ways. In the *catarrh*, the matter is more usually detained with the body, and rarely voided otherwise than by vomiting, and that usually only in small quantities, and in the beginning of the disengagement.

Signs of it. The general signs of the *choleric fever* and *catarrh* are a remarkable anxiety, and frequent complaints about the breast, as of a straitness and painful heat. A violent heat on the inside of the mouth, and insatiable and insupportable thirst, trembling, and convulsive motions of the joints, and violent deliriums. Dryness of the mouth and tongue is often to be terrible in this disease, that the skin cracks with it; and often the whites of the eyes, sometimes the whole body, become yellowish. The peculiar and appropriated symptoms of a *choleric fever*, strictly so called, are an universal languor and debility of the limbs.

A severe shivering first seizes the patient, and is soon succeeded by a very violent heat and raging pain in the head; and after the two first days, there usually are very terrible straining and reachings to vomit. The matter brought up at these times is caustic, acrid, and bilious, and inflames, and even ulcerates the fauces, and if voided upon a stone floor, effervesces violently. If this vomiting abates, there immediately comes on a diarrhoea, attended with a tenesmus, occasioned by the irritation of this sharp matter in the rectum. Faintings also are very frequent in this disease, especially where the vomitings do not bring up a sufficient quantity of the effuming matter. The peculiar and appropriated signs of the *catarrh*, strictly so called, are, that it is a violent and insatiable thirst, greater than that in any other fever. The bowels are always bound; and it is but very seldom that there is any tendency to vomit. The urine is reddish and turbid, and after standing some time, deposits a red sediment. Often there is a sensible pain and soreness in the praecordia, so that the patient cannot bear the least touch upon the breast; and usually, in the course of the disease there are faintings and violent convulsions.

Persons most subject to this disease are such as eat largely, and drink heavy and imperfectly fermented liquors after it. The *choleric fever*, properly so called, is most frequent with those of a choleric-languineous habit, and such as feed on high-seasoned meats, and drink abundance of wine or other strong liquors; and is often brought on such persons by their falling into a violent passion after a full meal. The *catarrh* peculiarly attacks the people of melancholic habits, who are much inclined to passion, but suppress it, and who are naturally collic. **Prognosis in it.** The simple *choleric fever* is attended with great danger, if not timely undertaken to be cured. But the *catarrh* is yet more fatal than it; and from Hippocrates's days has been accounted among the *feveres in diebus*, or fevers that very frequently kill the patient.

In many fevers nature is able to help herself, and succeeds best of all when left alone. But these are of that number of distempers in which the assistance of art is absolutely necessary, and out of which nature very seldom brings the patient safely when unassisted. The happiest turn this fever can take, is the copious discharge of the peccant matter by vomit; for when it goes downward, the febrile heat always increases, and the symptoms in general usually grow worse. When the reachings are violent, and the matter brought up is but small in quantity, then the patient is usually subjected to painful hiccup, and dangerous syncope and convulsions. When much bile is thrown up by vomit, and that not very badly coloured, and there is no diarrhoea, there is then little danger from the disease; and in general, coliciveness in this state of the disease is more eligible than a tendency to stools. The most violent the delirium is in these diseases, and the longer continued, always the greater is

the danger to the patient. And if the pains and burning heat suddenly cease, and a shivering and deflection of the spirits succeed, there is no doubt of a gangrene being coming on within. *Junker's Comp. Med. p. 322.*

Method of cure. The cure of these diseases consists in mitigating the violent sharpness of the humour, and promoting its evacuation; and finally, in abating the burning heat brought on by it. The utmost endeavours are first to be made to correct and alter the morbid matter. To this purpose, the several preparations of nitre, with the viscidulous powders and mucilaginous pitans, with small mixtures of lemon-juice, and frequent draughts of cooling and diluting liquors, are to be given moderately warm. If the coliciveness be too violent, cathartics of broth must be injected, with the addition of a little oil and salt; and, if necessary, small doses of rhubarb. To quell the febrile heat and emotion of the blood, the mixture simplex may be given with great success; and there is often a sensible good effect from the application of rags wetted in camphorated spirit of wine to the pit of the stomach. After the morbid matter is evacuated, the reachings to vomit may be allayed by gentle opiate. All hot medicines change the *bilious fever* into inflammatory ones; and the common sudorifics drive the morbid matter into the blood, and usually bring on almost immediate discolourings of the skin like those of the jaundice. Bleeding, though performed ever so early in the disease, seldom does any good, except only in remarkably plethoric habits.

FEVER, aliquotus, are those wherein the whole body is consumed and emaciated in no long time; the solid parts, with the fat, &c. melted down, and carried off by a diarrhoea, sweat, urine, &c.

FEVER, continuus. See *SYNCHUS*.

FEVER, dysentericus. See *DISSYLTERIA* *febris*.

FEVER, diarsy, is that which does not ordinarily hold beyond twenty-four hours. It is the gentlest of all fevers; is frequently got by too much exercise, or other external accidents. It is cured by rest alone, and keeping in bed. If it remain for several days, it is either called a *continua* *typhus*, or *simplex* *typhus*.

FEVER, epidemica See *EPIDEMIC*, *POLLENTIAL* *DISEASES*, *PELAGIC*, &c.

FEVER, eruptiva, are those which, beside the symptoms common to other fevers, have their crisis attended with cutaneous eruptions. Such are those of the small-pox, measles, the petechial, the purple or scarlet fever, and the military fever; the other symptoms are a grievous oppression of the breast, laborious short breath, obstinate waking, spasms, free thirous, cough, &c.

FEVER, put. See *HOSPITAL* *fever*.

FEVER, lenta, is a slow, durable fever, which extenuates and emaciates the body by insensible degrees. See *HECTIC* and *CONSUMPTION*.

It has three stages; the first, while it consumes the juices of the body; the second, when it exhauits the fleshy substance of its humidity; and the third, when it lays hold of, and destroys the solids themselves; in which last stage it is reputed incurable. Its effect is somewhat like that of a flame, first consuming the oil of the lamp, then the moisture of the wick; and lastly, the wick itself. But this fever is frequently considered as of the *symptomatic* or *standary* kind, arising in phthises, &c.

FEVER, inflammatoria. See *ACUTUS* *FEVER*.

FEVER, intermittens, is that which ceases and returns again alternately at stated periods, and is called also an *AGUE*. Agues are occasioned by effluvia from putrid stagnating water. They are also produced by eating too much stone-fruit, by a poor watery diet, damp houses, evening dews, lying on the damp ground, watching, fatigue, depressing passions, and the like. In a word, whatever relaxes the solids, diminishes the perspiration, or obstructs the circulation in the capillary or small vessels, disposes the body to this disease.

In this kind of fever, cold and heat, shivering and sweating, succeed each other; the paroxysms are attended with sickness, nausea, vomiting, head-ach, pain in the back and loins, &c. The paroxysms are acute, but the disease usually more or less chronic.

Sometimes the disease comes on suddenly, when the person thinks himself in perfect health; but it is more commonly preceded by listlessness, loss of appetite, and the other symptoms above recited. The quality of the urine after the fit characterizes these several species of intermittents: it is of a reddish colour, and lets fall a sediment exactly resembling brick-dust. It is sometimes frothy, and a pellicle or thin frothy skin appears on the top, and adhering to the sides of the glass in which it is contained.

While the fit continues, the patient ought to drink freely of water-gruel, orange-juicy, weak chamomile-tea; or, if

If his spirits be low, small wine-when sharpened with the juice of a lemon. His drink should be warm; and if twenty or twenty-five drops of laudanum be put into his drink, and given about half an hour after the commencement of the hot fit, it would promote his sweat, shorten the fit, relieve the head, and tend greatly to remove the disease. His food between the paroxysms should be nourishing, and easy of digestion; and his drink be small beer, adulterated with the juice of lemons or oranges, and sometimes a little weak punch. Moderate exercise will also be of great use.

In the cure of an *intermittent fever*, when it does not go off without medicine, the first object is to cleanse the stomach and bowels; for this purpose vomits should be taken before any other medicine; a scruple or half a dram of the powder of ipecacuanha will be sufficient for an adult, which may be taken two or three hours before the return of the fit, and repeated at the distance of three or four days during the operation, the patient should drink plentifully of weak chalybeate. If he be afraid to take a vomit, he must in this case cleanse the bowels by a dose or two of Glauber's salt, jalap, or rhubarb. At the beginning of an *intermittent fever*, when excessive heat, a delirium, &c. indicate an inflammation, bleeding may be proper; the intermittents that prevail in cold dry springs are sometimes blended with an inflammatory disposition; but the annual fevers are frequently combined with a principle of putrefaction, in which case bleeding would be improper; as the blood is seldom in an inflammatory state in *intermittent fevers*, this operation is rarely necessary.

After proper evacuations, the patient may safely use the Peruvian bark, which by the general consent of physicians, is allowed to be a specific for these fevers in all seasons, ages, and constitutions. Two ounces of the powder may be divided into twenty-four doses, and made into boluses with syrup of lemon, or mixed with red-wine, chamois-water, water-gruel, or any other liquor that is most agreeable to the patient. In a quotidian fever, one or three doses may be taken every two hours during the interval of the fits. In a tertian spasm, it will be sufficient to take a dose every third hour, and in a quartan every fourth. A smaller quantity of bark will suffice for a young person, and the dose must be adapted to the age, constitution, and violence of the symptoms. The patient should persevere in the use of this medicine till the disease is entirely overcome, and especially in autumn, or winter ages, which are much more obdurate than in the spring and summer. A cup of the following infusion drunk three or four times a day will greatly promote the cure; take an ounce of gentian root, half an ounce of calamus aromaticus, and as much orange-peel, with three or four handfuls of chamomile-flowers, and a handful of coriander seeds; bruise them together in a mortar, and use them in form of an infusion or tea. About half a handful of these ingredients may be put into a tea-pot, and a pint of boiling water poured on them; or two handfuls of the same ingredient may be put into a bottle of white wine, and a glass of it may be drunk twice or thrice a day. Those who prefer a decoction of the bark, may boil an ounce of it with two drams of bruised snake-root, and an equal quantity of salt of wormwood, in a quart of water till it is reduced to a pint; to the strained liquor may be added an equal quantity of red wine, and a glass of it taken frequently. In obdurate agues, and particularly unfavourable circumstances, it will be necessary to mix with two ounces of the bark half an ounce of Virginian snake-root, and a quarter of an ounce of ginger, or some other warm aromatic; but when the symptoms are of an inflammatory nature, the aromatic may be omitted, and half an ounce of salt of wormwood or salt of tartar may be added to the above quantity of bark. When children are affected with this disease, the bark may be rendered more palatable by mixing it with distilled waters and syrup, and sharpening it with the elixir or spirit of vitriol. It may be also given in the form of a chylifer. Dr. Lind recommends for an adult half an ounce of the extract of bark dissolved in four ounces of warm water, with the addition of half an ounce of sweet-oil, and six or eight drops of laudanum, to be repeated every fourth hour, or oftener, as occasion shall require. The quantity of extract and laudanum must be diminished for children. Children have been sometimes cured by wearing a waistcoat with powdered bark quilted between the folds of it, by bathing them frequently in a strong decoction of the bark, and rubbing the spine with strong spirits, or with a mixture of equal parts of laudanum and the sapaceous ointment. Professor Bergman, in his *Opuscula Physica & Chemica*, 1779, mentions several instances in which the most obdurate *intermittent fevers* that have raged in Sweden for some years past, and that would not

yield to the bark, have been almost constantly removed by the artificial Schaeffer-water, or other simple imbrications of water with fixed air. The following preventive will be of service to those who live in low marshy countries, or who are liable to frequent attacks of this disease: take an ounce of the best bark, Virginian snake-root, and orange-peel, of each boil in ounces bruise them all together, and infuse them five or six days in a bottle of brandy, Holland gin, or any good spirit; pour off the clear liquor, and take a wine-glass of it twice or thrice a day. Gentian root, or calamus aromaticus may also be chosen for the same purpose; all bitters, especially those that are warm and astringent, are anodynes to agues. Boech. Ham. Med. chap. 14, and Fuchs's Adv. &c. chap. 18, § 259.

In *intermittent fever*, a leucis, from Dr. Langridge's experiments, that the crystallization of the blood is not so viscid and tenacious, neither is the serum so viscid, saline, and acrid, as in acute continued fevers. The red globules abound more, and the corpus is more solid, although in quotidian than in tertian, and in tertian than in quartan. Med. Theor. and Pract. of Phys. p. 229.

The cold bath has been prescribed with success in a susceptibility to those who were recovering from obdurate *intermittent fevers*, to prevent a return of the disease. See Dr. Huxham's Obs. de Aere & Mole Epid.

Intermittent fevers are of divers kinds; as the QUARTAN, QUOTIDIAN, tertian, QUOTIDIAN, and TERTIAN. There are also *intermittent fevers* which only return every fifth day, or every sixth, or every seventh, and at other intervals.

Fevers, putrid, febris intermittens. In *Medicina*, a name given by Huxham to a peculiar species of acute fever, passed over in silence by the generality of authors, but by some called the *intermittent fever*, and by our Senham the *new fever*, *new fever*. This differs from other acute fevers, in that it is attended always with a diarrhoea, which, however, is febrile, and which it is very dangerous to stop; and in that it is not relieved by the antipyretic and diaphoretic medicines used in other fevers, much less by the best sudorifics; all these things expedite and make it worse, and the only things that give relief in it are gentle cathartics, and vomits that operate without violence. This fever, therefore, evidently shows the error of those faulty reasoners, who declare, that all acute fevers are to be cured by diaphoresis.

This peculiar species of fever, though unknown to many of the late writers, and called by Senham a new fever, was not unknown to the ancients. Hippocrates has left many things concerning it, as have also the later Greeks, and Celsius, and among the moderns, Dacier, Scennertus, Forelius, Riverius, Eschscholtz, Boerhaave, Stahl, Hoffman, and Linnæus, have all met with it, though they have given but very short and imperfect descriptions of it in their writings.

The generality of those who have written of this fever, have referred it to the malignant kind, from its being usually attended with severe and uncommon symptoms from the beginning, or from such being bred in on the course of an irregular treatment. The common method of curing fevers by diaphoretic medicines brings on in this, anxieties and strangeness of the precordia, with pains about the stomach, loss of appetite and delirium, with efflorescences of various kinds, particularly petechial spots; and these symptoms are not subsequently attended with death. But it is to be observed, that disease are to be carefully distinguished in their own symptoms; those which the physicians bring on being often very different from what nature would offer.

These fevers have their seat in the stomach and intestines, or if they have it any where else, it appears at least that their origin, which is in a putrid colic, is always much more easily educed and evacuated by these than by any other palliatives. Many of the diaphoretic mentioned by authors under peculiar names, are properly to be rejected, as to their cause, to this species of fever. The dysenteric fever is absolutely of this kind, and many of the petechial ones. The catarrhal fevers also are referable to this kind; and the continual quotidian and tertian, with the fevers described by the ancients under the names of *hemitana*, *altius*, *helieta*, *isidua*, and *hyria*, with the *tristitia*, nearly allied to the *hemitana*, and by some authors confounded together, the words being used as synonymous.

Symptoms of intestinal fevers. These are frequent shiverings when the patient is first seized with the disorder, which return at different and irregular intervals. After these, the tongue, teeth, and fauces are covered with a foul and viscid phlegm, the tongue, in particular, often looking yellowish and blackish with it; the patient perceives a continual disagreeable taste in his mouth

from this, and the people who are about him an ill smell. There is always a diarrhoea attending these fevers, and the faeces voided in it have a peculiarly offensive smell. The hypochondria are always distended, and often in pain; the patients are attended with violent trembling in their sleep, so that they are frequently waked in terror and uneasiness, and in tender subjects, their throats are very frequent while waking. Pains in the head and neck are also constant attendants of this distemper, and seem to take their origin from spasms. The urine, in the beginning of the disease, is of a natural state and colour, and afterwards becomes turbid, and deposits a muddy sediment during the whole course of the distemper.

These are the constant symptoms of these fevers; but beside these, there are sometimes other violent ones, such as violent anxieties of the praecordia, pains in the stomach, and in the side resembling those of a pleurisy, a loss of strength, a violent internal heat, and a continual convulsive or tremulous motion of the hands, with a subfultus tendinum, hiccough, and cold sweats, which are extremely dangerous symptoms, and presage a fatal period to the distemper.

Beside these, which are the common, and the additional symptoms of these fevers, there are yet some others often seen in them, which are merely accidental, and are owing to the improper management of the patient. It is a common error to give hot and sudorific medicines in these cases; the consequence of which is, that the peccant matter which was lodged before in the prime via is propelled into the blood, and not being able to make its way through the pores, it appears under the skin in form of petechiae or purple spots, or of purpura of a purple or reddish, sometimes of a livid or blackish colour. Under this circumstance, which is wholly owing to the ignorance of the practitioner, the distemper gets the name of a petechial or purple fever. Sometimes the same methods send the matter to the ears, where it occasions deafness; sometimes to the parotids and maxillary glands, where it forms tumours, inflammations, and abscesses of a very bad sort; and finally, if it be transferred to the brain, violent deliriums and a phrenitis are the certain consequence. Thus, according as this matter happens to be driven by this improper treatment to a more or less noble part of the body, it gives the symptoms of a more or less dangerous disease; and very frequently the patient seems to have a pleurisy or peripneumony, or an inflammation in the liver, spleen, or intestines, while in reality the cause of the disease is all the while the same; and there is no difference but that of the matter's settling on one or another part. Heister's Compend. Med. p. 83. and 97.

The method of cure. All hot medicines must be avoided, and the discharge of the peccant matter by the diarrhoea promoted by clysters, and by purging medicines. Some advise aloes, and other medicines of that kind; others fena and manna; some the purging salts; but most prefer rhubarb, given in often repeated small doses. Large draughts of the lubricating decoctions, such as barley-water and water-gruel, are to be given, and emulsions of sweet almonds and of the cold feeds. Small quantities of oil of sweet almonds are also to be given at times, and juleps of the cooling waters and syrups moderately acidulated, and powders of nitre, cinnamon, and the common absorbents, as crabs-eyes and the like, are to be given, to take off the pains and spasms, and to attenuate the acid matter. Bleeding in this fever is not necessary, unless in plethoric habits; and in those cases it must be done on the access of the disease; for if done after the third or fourth day, it is usually found to do more harm than good.

The diet in these fevers is not to be very thin and weak as in other acute fevers, but moderate nourishment is to be allowed, that the patient may retain his strength sufficiently to go through it: in the beginning of the disease, however, the patient has usually an aversion for food, and then it is not to be forced upon him; but when the stomach begins to require it, then it is to be given in a moderate quantity; and great care must be taken that nothing astringent or difficult of digestion be allowed, but light and innocent meats, and with these a little good wine to promote digestion. Some also have given frequent vomits, by small doses of ipecacuanha in these fevers, with very good success; and it is remarkable, that the purple fever, mentioned by Stahl and others, as peculiarly affecting lying-in women, and being very frequent in Saxony for a long time, was by Dr. Wagner and others cured by this method: its origin being found to be a viscid matter putrefying in the stomach and intestines; and therefore, the distemper being properly one of these *intestinal fevers*, was curable by the same methods with them; that is, by emptying the prime via.

Some, as Baglivi and Bar-chard, have called these fevers

intestinal fevers; but improperly, according to Heister; lib. c. p. 85.

FEVERS, malignant, are those in which the danger is much greater than the symptoms indicate, or in which the usual regular symptoms do not appear (nature being expelled with the malignity of the *serous matter*), but other foreign symptoms arise; as a pain about the stomach, and praecordia; a livid complexion, with the face much discoloured, &c. and sometimes effluences on the skin, &c.

Some authors, from microscopical observations, affirm, that in all malignant fevers, the blood is so corrupted, that swarms of little worms are generated therein, which occasion most of the symptoms.

In all malignant fevers the blood is too fluid. Blood-letting has here no place; emetics do well at first, afterwards iudicious and alexipharmics: blisters are recommended in the progress of the disease. See *delirant catarrhal fever*, *Miliary fever*, *Putrid fever*, and *Hospital fever*.

FEVER, miliary. See *Intestinal fever*.

FEVER, miliary, or purple, an acute, continual, and exanthematic fever, in which nature seems to be endeavouring to drive out the fulsome moribund matter to the surface of the body, by increasing her secretory and excretory motions. It takes its name from the small pustules or bladders, &c. which appear on the skin, resembling in shape and size the seeds of millet.

This fever is divided into two kinds, of the which, one is called *purpura rubra*, or the *red purple fever*; and the other by a very odd form of expression, the *purpura alba*, or *white purple fever*.

The *white purple fever* is usually malignant; it is easily complicated with the petechial fever, and in some places has of late years been found often to affect lying-in women. The *red purple fever* is much more benign and mild than this, and indeed often is attended with no danger.

These two species of *purpura* seem to differ as much as the small-pox and measles do from one another, the *white fever* of this kind being usually as much more fatal than the *red*, as the small-pox is more fatal than the measles; but as there are cases in which the small-pox is mild and benign, and the measles are sometimes dangerous, so in these diseases, out of the natural course, the white is sometimes mild, and attended but with a slight fever, while the red is fatal, and attended with a very high one. As the small-pox also has white pustules, and the measles only protuberances on the skin, so the *white purple fever* has also white regular pustules, while the red has only such protuberances as those of the measles.

The *miliary fever* is sometimes a primary disease; but it is much oftener a symptom of *gangraena malarum*, as the small-pox, measles, scarlet, putrid, or nervous fever; and in all these cases it is the effect of too hot regimen or medicines.

Signs of this disease. The white kind seizes the patient with a general shivering and coldness, and faintness of the praecordia, with great anxiety of mind, a low, quick pulse and loss of strength; and afterwards shews itself in alternate changes of heat and cold; and before the appearance of the eruptions, the patients are worse in respect of their anxiety and other symptoms; they are very restless, and sometimes delirious; the tongue appears white, the hands shake, attended frequently with a burning heat in the palms; and in child-bed women the milk generally goes away, and the other discharges stop; and they complain of a troublesome pricking or itching under the skin. The pustules usually first appear on the third or fourth day, sometimes later; and at their approach, there is first perceived a general redness of the skin; and after this the redness is collected into spots, in the middle of each of which there appears a white pustule; and these are often so copiously spread over the body, that they almost touch one another. These pustules are pellucid, and contain only a clear water, afterwards they grow yellowish; in child-bed women they are sometimes interspersed with pustules of a red colour: when these appear, the disease is called a *rasb*; and their eruption is usually attended with an acute fever; when these pustules have lasted four days, they cry away, and the places appear scaly, and the disease terminates. Sometimes, in people of humid habits, and such as have no fever, the pustules sweat out a white water.

The *red purple fever* seizes the patient in nearly the same way with the white; that is, with shivering and heat succeeding one another. It is also attended with a tension and pain in the back, and with a faintness of the breast and cough. The purple eruptions appear on the fourth, or on the seventh day, or later even than that, in form of small protuberances like millet seeds, and are attended at the time of their eruption with an itching within

within the skin: they are most numerous when the sweat is most abundant, as on the breast, back, &c. though the whole body is sometimes covered with them: the *fever* is not violent, and the sweat is copious, and of an ill smell. In some cases this disease is attended with no *fever* at all, and people go about their business with it, only complaining of an itching all over them. Some have violent pains of the head at the time, and are unaccountably sleepy and anxious: but these symptoms usually go off as soon as the eruptions appear properly: they remain fully out a few days, and then die away of themselves and the person finds himself as well as before. The *purple fever* of both kinds seems to have been more frequent of late than in the times of the earlier writers on medicine. The white kind in particular, some years ago, was in a manner epidemic in Saxony, and carried off great numbers, and particularly seized the lying-in women. Wherever the petechial *fevers* are frequent, there the white *purple fever* is usually also common. It often also mixes itself with the small-pox, and makes the case always greatly the worse, and all the symptoms more violent. The red *purple fever* is most frequent with young men, and such as lead sedentary lives, and are subject to violent passions: labouring people are scarce ever found affected with this disease. Among women, those of tender constitutions are most subject to it, and especially such as have been before subject to hysterical complaints. And the persons most subject of all to it are those of both sexes who live at ease and within doors, and by this means always are sending off the humours to the surface of the body.

Cause of it. These are a bad quality in the air, contagion from persons who have the disease, the driving back of sweats, and even the forcing them too violently by hot medicines: this too often happens to women in child-bed, and to persons in petechial *fevers*. To these are to be added also, the curing of the rheumatic and catarrhal disorders by a too cold regimen and method, and an omission of habitual bleedings, or by suppression of the menses, or discharges by the hemorrhoidal veins. The *miliary fever* is sometimes occasioned by violent passions and emotions of the mind: by great evacuations, a weak watery diet, rainy seasons, excessive use of cold, crude, unripe fruits, impure waters, and unwholesome provisions. In child-bed women this disease is often the effect of great coldness during pregnancy, and of immoderate use of green train, &c. But the more general cause is indolence.

Prognosis in it. The going back of the eruptions in the white *purpura* is very often fatal, and in the milder circumstance is usually attended with sphaculous alterations of the mind, and terrible mania; and if by means of remedies the eruptions appear again, and yet the symptoms occasioned by their going in do not disappear, there is great reason to suspect danger. The white *purpura* attending the petechial *fever* is very dangerous when the eruptions appear on the fourth day, but is less so when they appear later. The white *purpura* when not attended with a *fever*, is less dangerous than otherwise; but it is usually attended with distressing anxieties of mind, and with spastic motions.

The red *purpura*, when the eruptions are struck back, is not attended with such sudden danger as the white; but people usually have some convulsive motions attending it, and a great languor and debility of motion, and sometimes inflammations of the face, and dangerous quinseys; sometimes a dry cough, sometimes a heat of urine, or arthritic complaints, or a suppurative pleurisy, or a hemorrhagia; but all these symptoms go off as soon as the eruptions appear again.

If a diarrhoea comes on in the progress or decline of the disease, and is suddenly checked, it enlarges an opportunity. In child-bed women a diarrhoea is a very dangerous symptom, and the change of the colour of the urine from a yellow to a pale-colour is alarming; sleepiness is a favourable symptom.

Method of cure. This is to be the same both in the red and the white *purpura*, and is not different from that in other inflammatory *fevers*; namely, a gentle, but continual perspiration must be kept up, and this alone will often cure the disease.

The patient's food should be weak chicken-broth with bread, panada, fago, or ground rusk, &c. to a gill of which may be added a spoonful or two of wine. If his spirits are moderately high, his drink ought to be weak, as water-gruel, beam tea, &c. a decoction of two ounces of the shavings of harrishorn, and the same quantity of fassiparilla in two quarts of water, sweetened with white sugar, may be used as his ordinary drink. When the spirits are low, wine-whisky or small negus, sharpened with the juice of orange or lemon, should be allowed. If the *fever* has a putrescent tendency, the patient's strength must be supported with go-

rious cordials joined with acids; and if the putrescence increases, the bark must be administered. When the head is affected, the body should be kept open by emollient clysters.

On the days before the eruption of the *fever*, powders are to be given of nitre, diaphoretic antimony, and the absorbents, as crab-claws, and the life, and when the eruptions are out, which usually happens on the fourth day, the same powders must be given inter-changeably with gentle sudorific draughts: from all which, salutary-water, however, is to be carefully excluded. When the eruptions appear and return, camphor should be added to any other medicines. The most proper cordial in this case is good wine, and the medicines should be of the cordial and perspirative kind; and all heating ones should be avoided. A vomiting and diarrhoea, which sometimes attend this disorder, are mitigated by the saline draughts with fassiparilla and crab-claws. This method is to be continued, only giving the doses less frequently in the decline of the disease; and when it is wholly gone off, gentle purges are to be given thoroughly to cleanse the primæ viæ, and the patient is by degrees to be hardened to the air. It is to be observed, that all irritations of the bowels are as bad in these cases as in the small-pox or measles, and that even the use of the most gentle clysters should be very sparingly admitted. Bleeding can very rarely, if ever, be proper in this disease, as it commonly seems to be more of a putrid than of an inflammatory nature. Bleeds may be used through the whole course of the *fever*, but they should be small, and one applied at a time. However, if the pulse should sink remarkably, the pulses fall in, and the head be affected, it will be necessary to apply several blistering-plasters to the most sensible parts, as the inside of the legs and thighs, &c. People who are often subject to returns of the red or white *purpura*, would be right to use cupping with scarification frequently, by way of prevention; and when the cause of the disease is the suppression of some habitual evacuation, great care is to be taken to supply the place of that by bleedings, if it cannot be recalled in the accustomed way. This is to be done at different times to prevent relapses; and in general, a method of using gentle exercise, so as to promote a moderate sweat, is greatly preferable to the method used by some of clothing too warm, which rather promotes the disease, by inviting the humours to the surface.

Pregnant women should guard against coldness, use regular exercise, avoid all green trainy fruits, and other unwholesome things; now and then take a gentle laxative of manna or rhubarb, or cream of tartar, and bleed in the first months; and when in child-bed, strictly observe a cool regimen. *Linnæi's Conspect. Med. p. 327, and 329. Bachan's Dom. Med. chap. 21.*

FEVER, m. k. See *MILK*.

FEVER, nervous, called also *flow fever* and *fever on the spirits*, attacks persons of a weak relaxed habit, who neglect exercise, eat little solid food, study hard, or indulge in spirituous liquors. This *fever* may be occasioned by anything that depresses the spirits and impoverishes the blood, as anxiety and grief of mind, watching, intemperate thought, poor and irregular diet, unripe fruits, damp and unwholesome air, excessive evacuations, wet cloaths, great fatigue, and whatever obstructs the perspiration and causes a spasmodic stricture of the solids. The prodromic symptoms of a *nervous fever* are low spirits, want of appetite, lassitude, watchfulness, sighing, and dejection of mind; these are succeeded by a low, quick, and unequal pulse; a dry tongue, without any considerable thirst; alternate chills and shivering; giddiness and pain in the head; nausea and vomiting; pale urine, resembling dead small beer; difficult respiration, and slight alterations of mind. If in the progress of this *fever*, towards the ninth, tenth, or twelfth day, the tongue and skin become moist, with a plentiful perspiration and gentle purging; or if a suppuration happens in one or both eyes, or large pustules break out along the lips and nose, a favourable crisis may be expected; but the more dangerous and alarming symptoms are an excessive lassitude, wasting, tremors, with frequent fainting fits; a trembling tongue when put out, cold on the extremities and a fluttering or slow creeping pulse, a flaring of the tendons, an almost total loss of sight and hearing, and an involuntary discharge by stool and urine. The patient in this disease should be kept cool and easy, his strength and spirits must be supported by nourishing diet and generous cordials; and therefore wine should be mixed with his gruel, panada, &c. and strong wine whey or small negus, sharpened with the juice of orange or lemon, or mustard-whey, will be proper for his ordinary drink. Wine that is good and genuine is a very necessary and essential medicine in this *fever*; patients have been recovered from the most dangerous state by using in whey,

gruel, and negus, a bottle or two of strong wine every day. If a nausea prevails at the beginning, a gentle vomit should be given; and if the symptoms continue, it may be repeated any time before the third or fourth day. Those who cannot take a vomit should have their bowels cleaned by a small dose of rhubarb, or an infusion of leech and musina. Bleeding is generally improper in this disease, but blistering is highly necessary. Blistering-plasters may be applied in all stages of the fever with great advantage, and if the patient be delirious, he ought to be blistered on the head and neck. Blisters, however, are most proper towards the beginning, or after some degree of vapour rises, in which case it will be always proper to blister the head. A blister should be repeated every day for a copious of milk and water, with a five-fold or six to which may be added, if necessary, a spoonful of common salt. A violent loquacity, should it happen, may be checked by small quantities of Venice treacle, or by giving the patient for his ordinary drink the white decoction. If a military eruption happens, as it sometimes does about the ninth or tenth day, it should neither be checked by bleeding and other evacuations, nor pushed on by a hot regimen. In desperate cases, large doses of milk may be frequently repeated; or fifteen grains of nitre, with three grains of camphire, and six grains of salt of tartar, may be made into a bolus, with a little syrup, and given three or four times a day. In the intermission of the fever, the patient should take half a dram, or a whole dram of bark in a glass of red port or claret, four or five times a day. The bark may also be administered with other codices, in the following manner: take an ounce of Peruvian bark, half an ounce of orange peel, two drams of Virginian snake-root, and one dram of saltpetre; let them be powdered and infused for three or four days in a pint of the best brandy; strain the liquor, and give two teaspoonfuls of it three or four times a day in a glass of mild wine or negus. *Buchan's Dom. Med. chap. 19. Edinb. Med. Lib. vol. iv. p. 256. vol. ix. p. 26.*

FEVER, feriginosa. See **PERIPNEUMONY.**

FEVER, pestilential, are acute, contagious, and mortal diseases. Some will have the fever to be the disease or plague itself, others only account it a symptom of the plague. See **EPIDEMICAL DISEASES, PLAGUE, PESTIL FEVER, &c.**

FEVER, putrid, is a malignant fever, wherein, beside the other symptoms, on the fourth, or more frequently on the seventh day, petechia, or red spots, like fleas, appear chiefly on the breast, shoulders, and abdomen; the spots afterwards turn pale, then yellow, and to disappear. When they grow hard or black, they usually prove fatal.

This fever is contagious, and often epidemic. See **MALIGNA ENTERIAL FEVER, and PUTRID FEVER.**

FEVER, putrid, or putrid fever, is that to which women are subject in the time of pregnancy, and more especially in their lying-in; it generally makes its attack on the second or third day after delivery. The proximate cause of this disorder is an irritability and inflammation of the abdominal viscera, and principally of the intestines and the os uterini; and the remoter causes are a sudden emptying of the womb, in consequence of which the blood rushes into the empty membranes with an impetuosity that often excites inflammation; conglobated blood lodged in the uterus after delivery, obstructed lochia, a putrid air, access of the milk, inflammation of the breasts, absorption of acid milk, and retention of the excrements. But the chief predisposing cause of the inflammation of the intestines and os uterini in lying-in women to which this fever is owing, is the constantly increasing pressure of the gravid uterus against these viscera during the latter months of gestation, and in the time of labour; the ill effects of which are aggravated by accidental causes occurring after delivery, particularly by keeping the patient hot and confined, and giving her warm spices and stimulant cordials. This fever comes on like most others, with a cold or shivering fit, which is succeeded by restlessness, pain of the head, great sickness and bilious vomiting. The pulse is quick, the tongue dry, the spots denuded, and strength weakened. A great pain is commonly felt in the back, hips, and region of the womb; a sudden change takes place with respect to the quantity or quality of the lochia; and the patient is frequently loaded with a tenacious urine is very high-coloured, and discharged with pain, and in small quantity. The belly sometimes swells to a considerable size, and is always fore and tender. When the fever has continued for a few days, the symptoms of inflammation usually subside, and the disease acquires a more putrid form. A bilious or putrid diarrhoea, of an obnoxious and dangerous nature, comes on, and accompanies the disease through its future progress. In wo-

men of plethoric constitutions bleeding will be generally proper at the beginning; but it should be used cautiously, and not repeated, unless the symptoms of inflammation rise high; in which case a blistering plaster may also be applied to the region of the womb. During the cold in the patient should drink warm diluting liquors, and warm applications to the extremities of the body, as of heated bricks, bottles or bladders of water, &c. may be used with advantage. Emollient electuaries of milk and water, or of chicken-water, should be frequently administered through the course of the disease. Sometimes a vomit is given for evacuating the bile from the stomach; but it will be safely so moderate, a gentle laxative; the saline draught is never to be repeated for this purpose; and if it runs off by stool, or if the patient be restless, a few drops of laudanum, or some syrup of poppy may be added; if the stools should be so frequent as to exhaust the patient, a starch electary, with thirty or forty drops of laudanum in it, may be used; and he drink may be rice-water, with half an ounce of gum arabic dissolved in every pint; and if these fail, recourse must be had to the columbina-root, or some other astringent. Dr. Hume lays the principal stress in this disorder on the free and repeated use of purgative medicines, such as the sal catharticus, and clem. reini, or the tartarus emeticus, or vitum antimoniale, given in small doses every two or three hours, till an effectual discharge is procured; in consequence of which, he says, that the patient generally finds an immediate relief from pain, and sweats come out, prostr. humors fuscate, and the pulse becomes more calm and slow. When this disorder has arrived at the putrid state, antiputres should be used, and particularly the bark, in decoction or infusion, mixed with tincture of roses, or other gentle astringents; a flogist of the extract of bark, with half an ounce of spirituous cinnamon-water, two ounces of common water, and ten drops of laudanum, may be made into a draught, and given every second, third, or fourth hour. For a prevention of this fever, women in child-bed should be kept very easy; their food should be light and simple, and their bed-chamber clean, cool, and properly ventilated. To this circumstance of introducing fresh cool air into the chamber of the patient Dr. Hume ascribes his never having observed any petechia, exanthema, or any febrile eruptions attending this fever, nor a single instance of the miliary fever in the London lying-in hospital, where he has attended more than 1400 women after delivery. *Zuelan's Dom. Med. p. 587. &c. Hume's Treatise on the Puerperal Fever, 1772.*

FEVER, putrid, in a general denomination, under which may be comprehended the plague, spotted or petechial fever, pestilential, malignant, camp fever, &c. These are various names of the same kind of disease, according to the degree in which it prevails, or the different circumstances that attend it. Those who are most subject to this fever are persons of a lax habit, cold, phlegmatic constitution, and a melancholy disposition, or who are weakened by watching, fasting, poor or luxurious diet, hard labour, excessive venery, &c.

The remote causes of this disease are a stagnated and foul air, rendered noxious by putrid animal and vegetable effluvia; and, therefore, it prevails in camps, hospitals, gaols, large populous close towns, and low marshy countries; warm, sultry weather, with a moist atmosphere; unwholesome diet, as corrupted grain, putrid flesh or fish, and water that is become putrid by stagnation; a long continuance of animal food without a proper mixture of vegetables, whence dieters in long voyages, and the inhabitants of beleaguered cities are peculiarly subject to this fever; and an excessive use of alkaline salts and other medicines that dissolve the blood. The proximate cause is a dissolution of the blood, produced by putrid miasmata that are received into the lungs by inspiration into the stomach with the food, or being generated in some part of the body, are absorbed, as from putrid ulcers, &c.

The symptoms of the access of this fever are a remarkable weakness of body, without any apparent cause, and defection of mind. These are succeeded by nausea, and sometimes a vomiting of bile; a violent pain of the head, with a strong pulsation or throbbing of the temporal arteries; inflammation of the eyes, with a pain in the bottom of the orbits; noise in the ears; difficult respiration, accompanied with sighing; pain in the back and joints, and angina of the stomach; the tongue at first appears white, but afterwards livid and black; and the teeth are covered with a black crust. The skin, from being pale, becomes more highly coloured, and at last is very brown and blackish, and has more or less an offensive smell; the stools are extremely fœtid, and are sometimes of a greenish, black, or reddish cast. Livid spots appear on the skin, and there are sometimes violent hæmorrhages

or discharges of blood from the mouth, eyes, nose, &c. Patients in this disorder void worms both upwards and downwards, are affected with tremors, and become delirious.

Putrid fevers may be distinguished from the inflammatory by the smallness of the pulse, the great dejection of mind, the dissolved state of the blood, the puerile or purple spots, and the putrid smell of the excrements. They may be distinguished from the low or nervous fever by greater heat and thirst, by the higher colour of the urine, and by the greater violence of the symptoms. In some cases the inflammatory, nervous, and putrid symptoms are combined; and fevers of the inflammatory and nervous kind, by improper treatment, are converted into malignant and putrid ones. This fever seems to have no critical time for its termination; sometimes it terminates between the seventh and fourteenth day, and at other times is prolonged for five or six weeks.

The favourable prognostics are a gentle looseness after the fourth or fifth day, a warm mild sweat, small miliar pustules appearing between the purple spots, hot febrile eruptions about the mouth and nose, the rise of the pulse after the use of wine and other cordials, the abatement of the nervous symptoms, abscesses in the groin or parotid glands, and within the ears occasioning deafness towards the decline of the fever. The unfavourable prognostics are an excessive looseness, with a hard, swollen belly, large black or livid blotches, aphthae in the mouth, wild staring of the eyes, blindness, change of the voice, difficulty of swallowing, an inability to put out the tongue, a constant inclination to uncover the breast, cold clammy sweats, bloody sweat and saliva, black urine that deposits a black foamy sediment, flaring of the tendons, and frigid, ichorous, involuntary stools, attended with a coldness of the extremities.

The regimen and medicines proper for patients in this fever are such as counteract the putrid tendency of the humours, support their strength and spirits, and assist nature in expelling the cause of the disease, by promoting perspiration and the other evacuations. For this purpose they should be provided with a circulation of fresh air; and their apartments should be sprinkled with vinegar, lemon-juice, or any other vegetable acid; fumigations of myrrh, and other stomatic and antiseptic ingredients, may be used; and strong scented herbs, as rue, tansy, wormwood, &c. may be dispersed in different parts of the house, both for the relief of the sick, and for preventing the infection. The food should be light, as panada, &c. mixed with red wine, and sharpened with acids; and the drink should be orange, lemon, or vinegar-where, with the addition of wine in such quantity as the patient's strength requires; acidulated negus, or chamomile tea sharpened with elixir of vitriol or Clutton's spirit or oil of tartar. If the patient be colic, a tea-spoonful of cream of tartar may be put into a cup of his drink, or he may drink a decoction of tamarinds. The strength and spirits of the patient should be supported by frequently taking small quantities of proper aliments. If he be delirious, the hands and feet should be often fomented with a strong infusion of chamomile flowers, or of the bark. Bleeding is seldom necessary, but often hurtful in putrid fevers; and in cases where there are evident signs of inflammation in the beginning of the disease, it should be very cautiously admitted. The first medicines proper to be prescribed in this fever is an antimonial emetic, the operation of which may be succeeded by a dose of the ipecacuanha. Small doses of the emetic tartar may be repeated every second or third hour, with proper antiseptics and cordials; the safest and best cordial is good Rhenish or red wine; and one of the most powerful antiseptics is the Peruvian bark, which should be given early in this disorder, unless symptoms of inflammation should appear and regularly continue. An ounce of the powder may be mixed with half a pint of water, and the same quantity of red wine, and sharpened with the elixir of spirit of vitriol; to which may be added two or three ounces of syrup of lemon; and two table-spoonfuls of this mixture may be taken every two hours, or oftener. Those who cannot take the bark in substance may infuse it in wine. If a diarrhoea comes on, the bark should be boiled in red wine, with a little cinnamon, and sharpened with the elixir of vitriol, or gentle opiates and astringents may be used. Plenty of acids and medicines that promote a gentle perspiration are very beneficial in this kind of looseness. If the patient be troubled with a vomiting, a dram of the salt of wormwood dissolved in an ounce and a half of fresh lemon juice, and made into a draught, with an ounce of simple cinnamon water and a bit of sugar, may be given and repeated as often as it is necessary. Blitters are generally useful in the early stages of these fevers; when the puerile or spots suddenly disappear, the pulse sinks, and a delirium approaches, they may be applied to the head and inside of the legs or

thighs; but when there is any reason to apprehend a gangrene from the use of blisters, warm cataplasms of mustard and vinegar may be applied to the feet. When the glands swell, as they sometimes do in this disease, the suppuration of the swelling should be promoted by the application of poultices, and at a proper time they should be laid open, and the poultices continued. Ulcerous sores, of a livid appearance and putrid smell, that break out in the decline of this fever, may be gradually healed by the plentiful use of Peruvian bark and wine, sharpened with the spirit of vitriol.

Opening and antiseptic clysters, and mild laxative medicines, are proper to be administered during the progress of this disease. Camphor is useful both as an antiseptic and antispasmodic, particularly in the beginning of putrid fevers. Fixed air is a very efficacious antiseptic; and the introduction of it into the materia medica, in consequence of the experiments and discoveries of Dr. Macbride, Dr. Priestley, and others, promises to be of great use in a variety of disorders, and especially in those of the putrid kind. Mr. Hey of Leeds, in the year 1772, administered it with great success in a dangerous case of the putrid kind, by impregnating the water which his patient drank with fixed air from the atmosphere of a large vat of fermenting liquor, and by injecting clysters of it; collected from a fermenting mixture of clark and oil of vitriol. Dr. Percival of Manchester has also found the efficacy of fixed air in wines, &c. impregnated with it, for checking the febrile ferment, and lessening the putrid coliculous of the prime via in malignant fevers. Dr. Dobson of Liverpool, and Dr. Warren of Taunton, have likewise made successful trials of this medicine in putrid disorders. Dr. Hulse has successfully prescribed fixed air in cases of the gout, hectic fever, with consumption, putrid fevers, dysentery, and worms: he makes use of no particular apparatus for impregnating water and other liquors with this air; but he does this by the mere mixture of two liquors; these liquors are the solution of fixed alkaline salt and water, containing as much vitriolic acid as he finds a priori to be sufficient to neutralize the alkali, and to extract from it all its fixed air. He gradually and cautiously mixes these with each other, so as to prevent the effervescence or the dissipation of the fixed air as much as possible. His usual mixture consists of fifteen or thirty grains of salt of tartar dissolved in three ounces of water; to which are added three ounces of water properly acidulated by means of the vitriolic acid. In putrid fevers he also recommends half a dram of salt of tartar dissolved in three ounces of Peruvian bark, with the same addition of acidulated water as before. Hulse's Safe and Easy Remedy for the Stone, &c. 1778. See PNEUMONIA.

Mr. Magellan, in a letter to Dr. Priestley, recites a remarkable instance of the efficacy of fixed air thus administered in a putrid fever by a physician in Holland; the decoction of bark, which had been tried without effect, was afterwards mixed with the salt of tartar and vitriolic acid, and in three days the bad symptoms were removed, and the patient soon recovered. Prince Gallatin, the Russian ambassador to the States of Holland, has found by analyzing the bark, that it contains a large quantity of fixed air; and to this quality he conjectures the antiseptic virtues of it may be owing. Priestley's Exp. and Obs. in Nat. Philof. &c. 1779. p. 472.

Dr. Priestley's *mirra* air, which is a more powerful corrector of putrefaction than fixed air, may be found on trial to be of still greater service. For preventing putrid fevers a strict regard to cleanliness, a dry situation, sufficient exercise in the open air, wholesome food, and a moderate use of generous liquors, may be recommended. The infection also should be carefully avoided; and a person who is apprehensive of having caught it, should immediately take a vomit, and work it off by drinking plentifully of chamomile tea; and use for his ordinary drink an infusion of the bark and chamomile flowers, with strong negus, or a few glasses of generous wine.

Sir John Pringle observes, that the plague, and other pestilential fevers, hot scurries, and dysenteries, have very much abated in Europe within the last century; a blessing we can ascribe to no other second cause more than to the improvement of every circumstance relating to cleanliness, and to the more general use of ANTISEPTICS. In regard to diet too, it may be observed, that hopped beer, wine, and spirituous liquors, coming more into general use, have been a great means of suppressing putrid and malignant diseases. Greens and fruit are likewise more commonly used, and salted meats make a much less part of diet than they did formerly. To which may be added the more general consumption of tea and sugar, which are no inconsiderable antiseptics. With respect to the contagious nature of all putrid disorders, he thinks that the putrid effluvia received into the blood have a power of corrupting the whole mass: of which

he conceives the resolution of the blood, and sometimes even its smell in the advanced state of a malignant fever, the offensiveness of the fœces and other excretions, the livid spots, blotches, and modifications incident to this diætemper to be sufficient proofs. By the acrimony of this effluvia, the nerves are affected with various spasms; the pulse is always quickened, at first raised, and soon depressed. Buchan's Dom. Med. chap. 20. Priestley's Exp. and Obs. on different Kinds of Air, vol. i. Appendix, vol. ii. Ap. Pringle's Diætics of the Army, p. 293, 298, &c. Forster's Enquiry into the Causes, Symptoms, and Cure of putrid Fevers. See BILIOUS fever, HOSPITAL fever, &c.

FEVER, remitting, called also a *continued fever*, *æryxip*, and a *compound continued fever*, is that which continues some time without any gradual increase of heat, yet is liable to alternate fits of remission and aggravation, either stated and periodical, or irregular.

Of this there are divers kinds, denominated from the periods of returning, as the *remittent*, *continued quotidian*, *continued tertian*, *continued quartan*, &c. which are only a continued fever, whose access or fever fits return every day, or every other day, or every third day, or every fourth day.

Some enumerate divers other more complicated continued fevers, as the *double or triple quotidian*, which has two or three paroxysms every day; the *double or triple tertian* or *quartan*, which have two or three every third or fourth day; the *semiteridian*, by the Greeks called *hæmihæm*, which consists of a *continued*, and two *intermittent* fevers, of different kinds, viz. a *quotidian* and *tertian*; the patient, beside a *continued fever*, having an extraordinary fit every day, or every other day two.

Others divide the *remittent*, *æryxip*, or *compound continued fever*, into *simple* and *spurious*.

The *simple remittent* returns regularly, and is only distinguished from an *intermittent* in that the feverish heat in the interval of this latter is never quite extinguished; and that the paroxysms do not begin with so much chilliness and horror, and go off in profuse sweats.

The *spurious remittent* is attended with grievous symptoms of the nervous kind, resembling those of the rheumatism, colic, pleurisy, and other inflammatory and spasmodic diseases; beside immediate excretions, vomitings, diarrhoeas, &c. whence its returns are uncertain and variable.

The *simple* rarely, if ever kills; the *spurious*, frequently: sometimes it degenerates into a malignant *æryxip*.

The first is cured with the cortex Peruv. almost as infallibly as an *intermittent*: when it is brought to a regular intermission by bleedings, if there be signs of inflammation; or by a vomit, which may be repeated if the nausea continues, and by clysters or gentle laxatives: the febrile ferment being much the same in both, and the same medicine is found almost a cure, though not so speedy a remedy of the spurious, if properly applied. The diet and medicine in these fevers must be regulated by the predominant symptoms, whether they be inflammatory, nervous, or putrid. Whatever is of a heating quality should be avoided, as this fever is frequently changed into a continued one by a hot regimen and improper medicines.

These fevers prevail in low marshy countries abounding with wood and stagnating water; but they prove most fatal in places where great heat and moisture are combined, as in some parts of Africa, the province of Bengal in the East Indies, &c. where they are generally of a putrid kind, and prove very fatal. The most likely way to avoid the *remittent fever*, is to use wholesome and nourishing diet, to pay the strictest regard to cleanliness, to keep the body warm, to take sufficient exercise; and in hot countries to avoid damp situations, night air, and evening winds. Where it is epidemic, the best preventive medicine is the bark, which may be chewed or infused in brandy or wine, &c. Buchan's Dom. Med. chap. 22.

FEVER, scarlet, the name of an eruptive fever usually attacking young persons, and not attended with any great danger. When it is moderate in degree, it may be left to nature alone, and will go off very well without the assistance of medicines, only observing a good regimen; but if it be more violent, it is to be treated with more care: the patient is to be kept warm in bed, and to be made to drink large quantities of warm diluting liquors, acidulated either with lemon juice or spirit of sulphur or stibium, and the use of the attenuating and diluting medicines are to be given every four or six hours, together with the attenuating and gently diaphoretic powder; but during the course of the cure all hot things are to be carefully avoided, as well in food as medicine, for every thing of this kind renders the disease worse, when treated in the proper manner. The scarlet spots, after a few days,

dry off, and the skin scales away, and after this the patient usually is soon well. At this time two or three doses of some gentle purge are to be given; and if the weather be bad, the patient is to be confined to his chamber for some days afterwards, that the transpiration may be free and uninterrupted; by this means the worst kinds of this fever go well off.

But when this caution is neglected, it is very common to find the patient fall into a swelling of the belly after about three weeks, and sometimes into an anasarca; sometimes attended with a fever, sometimes without one, and often with tumours of the glands, and many other dangerous disorders. The urine in these cases becomes brown and turbid, and many are lost in this manner. But as this new disease, as it is usually called, though it is in reality no other than another period of the *scarlet fever*, owes its whole origin to the morbid matter which caused the first appearance of that, being in part retained in the body, the best method of cure is by those remedies which are able to carry those humours out of the body. Gentle purges are to be given at short intervals, and the way nature indicates is to be carefully followed, by giving diuretics in the intermediate days; for the brown turbid urine voided naturally in this case is an attempt of nature to carry off the matter that way. The bell of all diuretics in this case is a tincture of salt of tartar and spiritus nitræ dulcis mixed together, and taken twenty drops or more three times a day. In young subjects, who will not take purges in the common way, a clyster made of an infusion of sena purges them very well, and answers the purpose.

The common hot sudorifics are not to be given in these cases, for sweat is scarce to be obtained by any means in this disease: and great care is to be taken to keep the tumid parts from the cold air, otherwise the patient is often carried off at once by the chilling of them. If there be a fever with this second complaint, as is usually the case, the attenuating medicines are to be given in an afternoon and evening, and draughts of gently diuretic liquors to be drank after them.

In this, and in all other eruptive fevers, any thing that cools the patient is of the utmost consequence, and the bed is not to be new made, nor the shirt changed by any means during the course of the disemper. Immoderate heat, on the other hand, is almost as bad, and the middle regimen is the only proper one to be observed. The patient lying quiet, and being kept in an equal and moderate heat in all cases of eruptive fevers as well as in this, may be allowed in the beginning to walk about in his chamber, taking great care to keep out the cold, and need not be confined to his bed so long as his strength will permit his keeping up. Heilser's Compend. Med. p. 83.

FEVERS, slow, are gentle, but durable ones: they consume the patient by degrees. They usually arise from disorders in the lymphæ or pituita, whence Sylvius calls them *lymphatic fevers*.

The principal of these are the catarrhal, attended with a catarrh, cough, hoarseness, &c. and the scorbutic fever, into which acute fevers, and sometimes intermittent kinds degenerate. See NERVOUS FEVER and HECTIC.

The *slow fever*, or *febris lenta*, properly and distinctly so called, differs from the hectic fever in its origin; for it is generally produced by the degeneration of *diary fevers*, synocha, or quotidians improperly treated, and by the common intermittents violently and injudiciously suppressed by astringents; but the hectic fever is connected with the terrible accidents of vomice, empyema, and apopleptic inflammations of the viscera. Nor do they differ less in the continent cause; for in the *slow fever* there is not yet any actual hurt in the viscera, but only a tendency toward it, and such a disposition as may naturally bring it on; but in the hectic there is always either an obdurate furor or an apoplex, or a simple or fistulous ulcer. Junker's Conf. Med.

The symptoms of these diseases differ also as much as their causes; for in the *febris lenta* they are all mild, and in the hectic all terrible and violent. The *febris lenta* never is so violent a disease as to confine the patient long to his bed, and usually grows milder in the continuance than at first; but on the contrary, the hectic ever grows worse by duration; and finally, the *febris lenta* in all cases, except where it arises from the improper use of astringents in intermittent cases, is attended with profuse sweats; whereas the hectic, unless when cured by medicines of a wrong kind, is a dry heat, and never throws out any sweats till in the last stages. In *slow fevers* of this kind, the stools are thin, and not frequent, and usually have a mucous matter mixed with them. In the hectic, when complete, there usually come on violent diarrhoeas, which carry off the patient. The *lenta febris* is subject to degenerate into other diseases, and frequently

returns into the diſtemper, from which it firſt aroſe; but the hectic is ſubject to no tranſmutations. And finally, the *leſa febris* often goes off happily of itſelf, nature making her way through the obſtruction, and completing the cure. The hectic is uſually fatal.

Signs of the febris levis. There is a preternatural heat often ſcarce ſenſible to others, but very troubleſome to the patient; a dryneſs of the mouth, and conſtitual thirſt; a loſſes of appetite, and waſting of the ſtrength; a general ſwellneſs of the face, except for a ſwelling of the cheeks; a waſting of the ſteth; violent ſweats in the night; and a redneſs and foulneſs of the urine when firſt made, but afterwards a precipitation of a pale, red ſediment, and the remainder then is clear above.

Perſons ſubject to it. Theſe are principally young men who are of a plethoric habit, and who have had an ephemeræ or ſynocha, or ſome other fever of that kind, improperly treated with too hot medicines; and ſuch as in fevers of other kinds, where nature produced copious ſweats, have ſuppreſſed them either by medicines or by an improper regimen; and finally, people worn down and exhauſted by violent hæmorrhages.

Progreſſus of it. This kind of fever, when it ariſes from an intermittent, and, in fine, returns into its old ſtate again, is attended with very little danger; but there is much more danger where it continues long in its own appearance, or where it degenerates, as it too frequently does, into an acute one. The degeneracy of this fever into a hectic, is of all other conditions of it the moſt dangerous; and this is not always readily diſtinguiſhed; this is, it may be ſuſpected, the caſe when the patient's appetite returns, and yet all the ſymptoms continue; eſpecially if there be added to them a ſhort cough, and difficulty of reſpiration; and when there is a ſenſation of a weight in the abdomen, and it is painful to lie otherwiſe than on one ſide, or in ſome particular poſture.

Method of cure. The firſt thing to be done is to attempt the reſolving of the ſtasis, as by pimpernel and elecampane roots, by the gentle alexipharmics, and by the neutral ſalts, as the tartarum viſtolum, and the like. The viſcid ſecondities left by intermittent fevers are to be carried off by firſt attenuating and inciding them by the gums, as ammoniacum and the reſt; and the tone of the viſcera is to be finally re-eſtabliſhed by the gentler chalybeats and ſtomachics.

When the caſe ariſes from an acute fever, powders of tartar of viſtrum, crabs-eyes, and diaphoretic antimony, with gentle cathartics in the intermediate days, will often complete a cure; when it ariſes from an intermittent, no happier means can be deſired for the cure than the bringing it back to its old ſtate of the intermittent again. Emmetur ſays, that the volatile alkali, ſuch as ſpirit of ſal ammoniac, have a great power this way; and Stahl propoſes to effect it by a habit of drinking an infuſion of elecampane, pimpernel, centaury, orange-peel, and ſena, with a ſmall quantity of ſubarb and black hellebore, in wine.

Finally, when this caſe has been brought on by violent hæmorrhages, the analeptics alone are to be depended upon, with the ſtomatic powders, to abate the ſweats, and the lighter ſtimulants of ſteel to reſtore the loſt tone of the ſolids. Junker's Conſp. Med. p. 384.

It is obſerved in the Periodical Eſſays of Edinburgh, that in the flow fevers which prevailed in and near that place, November 1731, attended with a violent pain in the head, a ſmall quick pulſe, deliriums, and watchfulneſs; ſeveral of the elder ſort died, but of the younger, many voided worms and recovered. See Med. Eſſ. Abridg. vol. i. p. 66.

FEVER, *ſtationary.* See STATIONARY.

FEVER, *tert.* See DENTITION.

FEVER, *ſtationary.* See BURNING FEVER.

FEVER, in the Manger. is a diſorder to which horſes are very ſubject from a variety of cauſes. The ſymptoms which denote the horſe to be afflicted with a fever are great ſtillneſs, by reaſon of which he ranges from one end of the rack to another, beating of the flanks, redneſs and inflammation of the eyes, a parched and dry tongue, his breath is hot, and of a ſtrong ſmell, he loſes his appetite, and nibbles his hay without chewing it, and is frequently ſmelling to the ground; he dungs often, but little at a time; and his dung is uſually hard, and in ſmall pieces; he ſometimes ſtals with difficulty, and his urine is highly coloured; he is always craving for water, and drinks often, but little at a time; and his pulſe beats full and hard, fifty ſtrokes and more in a minute. The firſt part of the cure is bleſting; and the quantity, if the horſe is ſtrong, and in good conſtitution, ſhould be two or three quarts; then give him four times a day a pint of the following infuſion: take bium, ſage, and chamomile flowers, each a handful; an ounce of liquorice root, ſliced, and three ounces of nitre; and

pour on theſe ingredients two quarts of boiling water; when cold, ſtrain it off, and ſqueeze into it the juſe of two or three lemons, and ſweeten it with honey, or an ounce of nitre mixed into a ball with honey may be given three a day inſtead of the drink, and waſhed down with any ſmall liquor. The horſe's diet ſhould be ſoaked in ſmall quantities, or dry bran ſprinkled with water, or a handful of picked hay may be put into his rack. His water ſhould be a little warmed, and given to him often, and in ſmall quantities; his covering ſhould be moderate. If the horſe reſuſes to feed, in a day or two more blood ſhould be taken away, and the drink continued, to which may be added two or three drams of ſaffron. If his dung continues hard and knotty, a clyſter may be given, prepared by boiling two handfuls of marſhmallows, one of chamomile flower, and an ounce of fenel-feed, in three quarts of water, till it be reduced to two, and adding to the ſtrained liquor four ounces of treacle, and a pint of linſeed oil, or any common oil. This clyſter ſhould be repeated every other day; and on the intermediate day the following drink may be given: take of cream of tartar and of Glauber's ſalts, of each four ounces; diſſolve them in barley-water, and add an ounce or two of ſeſitive ſellary, or a dram or two of powder of jalap. By purſuing this treatment the horſe will begin to recover; and nothing more will be found neceſſary than to give him gentle exerciſe in the air, and plenty of clean litter in the ſtable. There is another fever to which horſes are ſubject, more dangerous than the former: this is a flow fever, attended with great depreſſion; the horſe is ſometimes inwardly hot, and outwardly cold, and at other times hot all over; his eyes appear moſt and languid; his mouth is continually moiſt, ſo that he has no inclination to drink, and he is ſatisfied with very little. He eats little, moves his jaws in a feeble looſe manner, and grates his teeth; his body is commonly open, his dung looſe and moiſt; his ſtaling irregular, ſometimes little, and at other times profuſe, and his urine pale, with little or no ſediment. Theſe fevers are attended with a running at the noſe, and the matter diſcharged is of a reddiſh or greeniſh ſulky colour, and of a confidence-like glee. About three pints of blood ſhould be firſt taken away, and bleeding repeated according to the ſtrength and ſuſtained of the horſe, the degree of his cough, or any tendency to inflammation. After this the nitre drink already preſcribed may be given, with the addition of an ounce of ſnake-root, and three drams of ſaffron and camphor diſſolved in a little ſpirit of wine.

The horſe's diet ſhould be ſcalded or ſprinkled with water, and the belt hay, with which he ſhould be fed by hand, as he ſometimes cannot lift up his head to the rack. Drinking plentifully will greatly contribute to diſſolve the blood; but if the fever ſhould increaſe, balls of contrayerva root, myrrh, and ſnake-root, powdered, of each two drams; ſaffron, one dram; mithridate or Venice treacle, half an ounce, mixed with honey, ſhould be immediately given twice or thrice a day, with two or three horns of infuſion of ſnake-root ſweetened with honey; to a pint and a half of which may be added half a pint of treacle water or vinegar; if theſe balls produce no ſenſible effect, let a dram of camphor and of caſtor be added to each of them; or the following drink may be ſubſtituted in their ſtead for ſome days; take a dram of camphor diſſolved in one ounce of rectified ſpirit of wine; then gradually pour on a pint of diſtilled vinegar warmed, and give it at two doſes. If the horſe ſhould be ſedative, recourse muſt be had to clyſters or the opening drink; and if he purges to a conſiderable degree, diſcordium may be added to his drink inſtead of the mithridate. The operation of medicines in this diſeaſe is much promoted by plentiful drinking; the horſe's ſtaling ſhould be reſtrained when it is conſiderable and weakening, by proper ſtringents, or by mixing lime-water with his drinks; and when he is remiſs in this reſpect, and ſtals to little at a time, a ſwelling of his body and legs, two or three of the following balls may be given at proper intervals, with a decoction of marſhmallows ſweetened with honey: take of ſil prunella or nitre, one ounce; juniper-berries and Venice turpentine, of each half an ounce; and make theſe ingredients into a ball with oil of amber. If with this treatment the horſe's ſkin feels kindly, his ears and feet are moderately warm, his eyes bright and lively, his noſe becomes clean and dry, his appetite increaſes, he lies down well, and ſtals and dungs regularly, there is a fair proſpect of a ſpeedy recovery; but he ſhould be fed ſparingly, and his diet ſhould be light, and increaſed by degrees as he gains ſtrength.

If the fever ſhould intermit, give an ounce of Jeſuit's bark in the interval of the fits, and repeat it every ſix hours till the horſe has taken four or fix ounces. Baſtlet's Farriery, and Faimet's Dictionary.

FEVER-ROOT, *trifolium*, in *Botany*. See *Fago IPECACU-ANNA*.

FEVER-TREE. See *ERYNGO*.

FEVERFEW, *Matriaria*, in *Botany*, a genus of the *frangulae polyandrae superfluae* class. Its characters are these: it hath a compound flower, the ray or border is composed of female half-flowers; and the disk, which is hemispherical, of hermaphrodite flowers: the female half-flowers are tongue-shaped, are inserted in three parts at the end, and have a naked germen; the hermaphrodite flowers are tubular, funnel-shaped, and cut into five parts at the limb; they have each five hairy short filaments, and an oblong naked germen; the germes of both turn to single oblong seeds. There are two species, comprehending several varieties. *Linnaeus enumerates seven species.*

Feverfew grows naturally on banks in several parts of England, but is frequently cultivated in physic gardens to supply the markets.

The leaves and flowers of this plant, the *matricaria parthenium* of *Linnaeus*, have always been allowed one of the first places among the hygieinic and uterine plants, and hence it derives its name from *matris*, the womb. It is prescribed in powder from a scruple to half a dram for the dose; but the much better way is in a slight infusion made in the manner of tea. Taken in this easy manner for a continuance of time, it will bring the menses, though subject to be interrupted and irregular, to their true period; and will remove a number of complaints, the natural consequence of such an irregularity.

It is also an agreeable, warm, aperient, carminative bitter. It strengthens the stomach, and disperses flatulencies, and the expressed juice is said to kill worms. Some likewise commend it in disorders of the head, and in all nephritic complaints. Hoffman gives it great praises, used as a febrifuge. There were formerly kept simple water and syrup of *feverfew* in the shops; but at present they are wholly disused, and the dried herb only kept ready for fomentations, and sometimes as an ingredient in clysters. The virtues of *feverfew* are in some degree similar to those of chamomile.

Many species of this plant are cultivated in gardens for the beauty of their flowers. They are propagated by sowing them in March, on a bed of light earth; when they are come up, they should be transplanted out into nursery-beds, at about eight inches asunder; and in the middle of May they should be removed into the flower-beds where they are to stand. They flower in July and August; but they should not be permitted to seed, which always weakens and often destroys the roots; so that the stalks should be cut down to the ground when the flower decays.

FAYE-RIVER, *Agardh*, *parthenium*, in *Botany*, a genus of the *monandra pentandra* class. Its characters are these: it hath a flower composed of hermaphrodite flowers and female half-flowers, which are included in a common five-leaved spreading envelope. The hermaphrodite flowers which form the disk have one tubular petal cut into five parts at the brim; they have five hair-like filaments, the length of the tube. The germes is situated below the flower, and is scarce visible; supporting a slender style, having no stigma: these flowers are barren. The female flowers which compose the rays or borders are stretched out on one side like a tongue; these have a large heart-shaped compressed germ, with a slender style, crowned by two long spreading stigmas. These flowers are succeeded by one heart-shaped compressed seed. There are two species. Miller.

The first sort grows wild in great plenty in the island of Jamaica, and in some other of the English settlements in the West Indies, where it is called *malva veronica*, and is used by the inhabitants as a vulnerary herb. The second sort grows plentifully in several parts of the Spanish West Indies, from whence the seeds have been brought to Europe. These plants make no great appearance, so are seldom cultivated but for the sake of variety.

FEUILLANS, an order of religious clothed in white and going bare-foot, who live under the strict observance of the rule of St. Bernard.

The name was occasioned by a reform of the order of Bernardines, first made in the abbey of *Feuillans*, a village in France, five leagues distant from Thoulouse, by the fleur Barriere, who established it about the year 1580. It was approved of by pope Sixtus V. and the popes Clement VIII. and Paul V. granted it its particular privileges. King Henry II. founded a convent of *Feuillans* in the Faubourg St. Honoré at Paris in 1569.

There are also convents of nuns who follow the same reform, called *Feuillantes*, the first of which was established near Thoulouse in 1590.

FEUILLE DE SEU, in *Herbology*, expresses that an ordinary, as a scellé, pale, or the like, is indented only on one side; because it then looks like the leaf of a saw, as the French phrase imports.

FEVILLEA, in *Botany*, the name of a genus of plants of the *diandra pentandra* class, called by *Plumier* *shandiviva*; the characters of which are these: it produces male and female flowers distinct on the same plant; in the male flower the perianthium is campanulate; it is composed of one leaf, and is round at the bottom, but expanded at the mouth, where it is divided into five segments; the flower consists of one leaf, and is of the rotund kind; it is lightly divided into five segments at the edge; these are convex and tumid, and the umbilicus is covered with a double flax, the filaments are five filaments. In the female flowers the cup is the same as in the male; the flower itself is also the same, but that the flax which closes the base, is composed of five coarcted leaves. The fruit is a very large fleshy berry with a hard bark, and is of an oval obtuse figure, and surrounded with the calyx. The seeds are flat, and of an orbicular form. There are two species.

FEWEL. See *FUILL*.

FEWMET. See *FUMET*.

FIANTS, or *FUANTS*, the dung of a badger, fox, and other vermin.

FIARSING, in *Ichthyology*, a name given by the Swedes and Danes to the fish generally called the *drum* *marinus* and *arounis marinus*, the sea-dragon, and the sea-spider. It is a species of the trachinus, according to Arted, and is distinguished from the others by its lower jaw being longer than the upper, and without beards.

FIAT, in *Law*, is used for a short order or warrant of some judge for making out, and allowing certain processes. Thus, if a certiorari be taken out in vacation, and rested of the precedent term, the *fiat* for it must be signed by a judge of the court, some time before the return day of the subsequent term, otherwise it will be irregular. There is no need for the judge to sign the certiorari itself, but only where it is required by statute.

FIAT JUSTITIA, is an order granted on a petition to the king for his warrant to bring a writ of error in parliament, in which case he writes on the top of the petition *fiat justitia*, and then the writ of error is made out; &c.

FIATOLA, in *Ichthyology*, a name given by the Italian fishermen to the *STOMATEUS*.

FIBER, in *Zoology*, or *fiber* *coffer* of *Linnaeus*, *bovier*, has strong cutting teeth, short ears hid in the fur, blunt nose, hair of a deep chestnut brown, tail broad, almost oval, compressed horizontally, and covered with scales; the forefeet are small, and the hind-feet large; the length of the animal, from nose to tail, is about three feet; the tail is eleven inches long, and three broad. See *BRACHYON*, and *Tak. II. Quad. fig. 13*.

FIBRA *arbor.* See *LEX*.

FIBRILLAE, in *Natural History*, the name of a class of fibrous bodies; the greatest part of which have been very improperly called by the writers of *foliis*, *fibrosae* *talae*, they being of a very different substance and structure of parts from the scales, and having none of their distinguishing characters.

The word is derived from the Latin *fibre*, *a fibre* or *filament*, these bodies being all composed of arrangements of parallel filaments or fibres. See *Tak. of Fossils, Class 1*. The *fibrillae* in general are solids composed of parallel filaments, usually remaining to distinct as to preserve in the whole masses a thread-like texture, but sometimes uniting to form plates or flakes resembling those of the scales in external figure. They are bright, and in some degree transparent, not giving fire with steel, nor fermenting with, or soluble in acid menstrua. Hill's *Hist. of Yell.* p. 33.

Of this class of bodies, there are two distinct orders, and under these four genera: To this class belong the *amiantos*, *albiclos*, *laminides*, and *richides*.

FIBRE, in *Anatomy*, a simple part of the animal body, called also *filamentum*, and when very small, *filicula* or *capillamentum*.

A *fibre* is a long, slender, white thread, which being variously interwove or wound up, forms the various solid parts of an animal body; so that the fibres are the filament or matter of the animal.

Anatomists usually distinguish four kinds of *fibre*, viz. *carneae* or *fleshy*, *nerveae*, *tendinae*, and *osseae* or *bony*; of one or other of which all the other parts consist. See *FLESH*, *NERVE*, *TENDON*, *BONE*, *MUSCLE*, and *SKELETON*.

Fibres, again, are divided with respect to their situation into *direct* or *longitudinal*, which proceed in right lines; *transverse*, which cut or go across the former at right angles; and *oblique*, which intersect or cross them at unequal angles.

Some anatomists reduce the animal *fibre* to two species, viz. *muscular* or *nerve*, and *nerve* or *fleshy*.

FIBREAE, *nerveae*, are the minute threads whereof the nerves are composed. They arise from the medulla of the brain, as that does from the cortex; and that again from the

the last finest ramifications of the carotid and vertebral arteries; so that, it is probable, these nerves are, in reality, only continuations of those arteries.

From every point of the cortex there arises a fine medullary *fibrilla*: these, uniting in their progress, form the medulla of the cerebrum, cerebellum, and oblongata; and *fibrille* arising from each point of these again, form the spinal marrow.

From the medullary substance of all these parts arise nerves, which are combinations, or assemblages, of a number of these minute medullary *fibrille* inclosed, after they are got out of the cranium, in a common membrane, or coat, from the pia mater; and it is probable, that, to each nerve, there concur *fibrille* from all three; as, also, that these *fibrille* are so many fine hollow tubuli, or canals, for the conveyance of a fine juice, or spirit, from the brain, throughout the body. See NERVE.

FIBRÆ, muscular, are those whereby the muscles, or fleshy parts of the body, are composed. Every muscle is divisible into other less ones; and these into others, still less beyond all imagination. The last and smallest are the muscular *fibræ*; concerning which it is questioned, whether or not they be vascular.

Mr. Leuwenhoek says, that he could plainly distinguish the fibrils, of which each muscular *fibræ* is composed, to be vascular; for, if he cut across their length, the light appeared through the mouths of the vessels; but if he cut them obliquely, no light was to be seen; and he also found that each fibril is invested with a minute membrane, which is only a conjuncture of blood-vessels; conveying juices and nutrition to it, though their fineness renders them invisible; and that the *fibræ* are through their whole length encompassed with circular wrinkles. Phil. Trans. N° 267. Leuwen. Op. tom. i. p. 49. tom. ii. p. 63, &c. ed. 1772.

That the muscular *fibræ* are vascular has also been supposed by Malpighius Borelli, Gorter, and Hooke, to whom they appeared like strings of pearls; and also by Dr. A. Stuart, in his treatise De Motu Muscularum, where from such a structure, and by the influx of the nervous fluid, he endeavours to account for the elastic force, the contraction, distension, and all the actions of the MUSCLES.

Now there are nerves propagated to every muscle, and distributed through the body thereof; so that there is no assignable point wherein there is not somewhat of a nerve. Add, that all the nerves here disappear; and that in other parts of the body, the extremities of the nerves are expanded into membranes. It is therefore probable, that the muscular *fibræ* are only continuations of the nervous ones.

The animal *fibræ* have different properties; some are soft, flexible, and a little elastic; and these are either hollow, like small pipes; or spongy, and full of little cells, as the nervous and fleshy *fibræ* above mentioned. Others are more solid, flexible, and endowed with a strong elasticity, or spring; as the membranous and cartilaginous *fibræ*.

A third sort are hard and inflexible; as the *fibræ* of the bones.

Of all these, some again are very sensible, and others wholly destitute of sense; some few very small, as not to be easily perceived; and others on the contrary, so big, as to be plainly seen; and most of them, when examined with a microscope, appear to be composed of still smaller *fibrille*.

These *fibræ* first constitute the substance of the bones, cartilages, ligaments, membranes, nerves, veins, arteries, and muscles. And again, by the various texture, and different combination, of some or all of these parts, the more compound organs are framed; such as the lungs, stomach, liver, lungs, and arms, the sum of all which make up the body.

The great property of *fibræ* is elasticity, or a power of contraction, after the distending force is removed; upon the knowledge of which that of the animal mechanism greatly depends.

To understand this, it may be observed, that any membrane or vessel may be divided into very small *fibræ*, or threads; and that these threads may be drawn out into a very considerable length, without breaking; and that when such external force is removed, they will again restore themselves to their proper dimensions. It is farther also manifest, that this property is preferred to them by a convenient moisture; because if one of these threads be dried, it immediately loses it; so that upon the application of any force to stretch it, it will break; its lying soaked in liquor too much will, on the other hand, render it flaccid, and destroy all its power of restitution, when distended.

Now, some hints of that configuration of parts, upon

which this property depends, Dr. Quincey maintains, may be had from the contrivance and properties of a syringe; with the reason why it is so difficult to draw back the embolus, when the pipe is stopped; and the necessity of any liquor's following it, wherein the pipe is interposed. All that is necessary hereto, is, that the embolus be so exactly adapted to the inner surface of the barrel, as to prevent any air passing between them, when it is drawn up; so matters not what figure the barrel is of, so that the embolus be well fitted to it. A case of syringes therefore might be contrived, wherein every barrel may also serve as an embolus to the exterior one, which immediately includes it.

In this manner it is not difficult to imagine a continued series of particles to put together, that they may be moved and drawn upon one another, without suffering the air immediately to enter into the interstices made by their distraction; whereupon as soon as that force, which drew them, is removed, they will, for the very same reason as the embolus of a syringe, rush up again into their former contacts.

As suppose A B (Tab. Nat. Hist. fig. 6.) two particles touching one another in *e f*, and C D two others, covering the opposite sides of their contacts. It is also to be supposed, that on the other sides they are covered with other particles in the same manner, as by C D, so that the places of their contacts are on all sides covered from the air, or the insinuation of any fluid body.

If now A B by an external force, greater than that of their cohesion, be drawn from each other, as far as G I and H X (fig. 7.); as soon as that force is removed, they will again run into their former contacts in *e f* (fig. 6.); that is, if they be not so far separated as to bring their transverse surfaces to coincide with C and D; for then the air, or circumambient fluid, will interpose, and prevent their re-union; so that by this contrivance, so much of A and B as is inclosed by other surrounding particles, is as the embolus of a syringe, and the particles surrounding them as its barrel. And therefore when A and B are distracted from their contacts in *e f*, it will be with some difficulty; and when the distending force is taken away, they will again run into their former contacts; just as the embolus of a syringe, and for the same reason.

It is not rightly contended, that this must exactly be the texture of a *fibræ*, but only something like this; whereby the interstices of the interior orders are covered by the exterior in such a manner, that when the thread is distended, that is, when its constituent parts are drawn from their transverse contacts, neither the air, nor any other external fluid, can get between them, so as to hinder their re-union as soon as such force is withdrawn; that is, if their distraction, as was before said, be not so far as to bring their transverse surfaces to a coincidence with one another; for then the circumambient fluid will interpose, that is, the thread will be broke.

But besides this peculiar arrangement of a determinate set of particles to compose the main substance of an animal *fibræ*, endowed with the properties above mentioned; it seems not at all unreasonable to conjecture, that into their composition there also enters a common capsule, or covering, which assists in the wrapping up, and holding together, those fasciculi, or assemblages of particles already described, not much unlike the pericosteum of the bones; the texture of which covering, resembling that of a net, cannot any ways hinder either the transverse, or longitudinal distractions of the other parts.

Supposing this, then, the texture of a *fibræ*, it will be necessary to consider what further requisites are needful to put them into that state which they are in, in a living body; to shew how they are maintained in continual motion, and what are the consequences of it.

And, 1. It is necessary to take notice, that all the *fibræ* in a living body are in a state of distention; that is, they are drawn out into a greater length than they would be in, if separated from the part, and taken out of the body; which is demonstrable upon any solution continui, as in the transverse division of a nerve, or artery; for immediately the divided parts run up, and leave a great distance between them; and the fluids contained between them, upon such contraction, are squeezed out. This also shews, that their natural distractions are owing to some fluids being propelled into the vessels which they compose, with a force greater than their endeavours of restitution, so far as to obtain a close contact of all their transverse surfaces, but yet less than that which is necessary to distract them, so as to bring them into a coincidence; for then the vessels would break.

2. This state of distention must necessarily leave vacuola between all the transverse surfaces; as between G I and H K (in fig. 7.) which may be represented by the fe-

veral series of particles (fig. h.) which vacuola will continue as long as the longitudinal surfaces of the component parts continue to close to one another, as to prevent the infiltration of any foreign matter, how subtle soever, between them.

For the same reason, therefore, as when the embolus of a syringe is drawn, and the pipe is stopped, there must be continually a *series repulsa*, or an endosmotic contraction. There is also this further necessity of their being continued in a state of contraction because if they were closely to touch one another in all parts, they could not be put into, and continue in, their undulatory motions, which they are always in, in a living body, without being affected in their figures and contortures.

3. It being manifest, that all animal fibres are continued by the perpetual successive impulse of the fluids, in such undulatory motions, before the necessity of their distention, they must also necessarily be continually enlivened with some convenient fluid, because otherwise their continual attritions against one another would wear them out, as well as render it difficult to move them; the fluid also, for this purpose, must be very soft and subtle, because otherwise it could not infiltrate itself into all the interstices of the fibres, without so far separating their parts, as to be inconsistent with that cohesiveness and mechanism here laid down.

Upon this view there offers a very natural explanation of several terms, much used by mechanical writers, such as *diffusion, imbibition, distention, undulation, rarefaction, contraction, relaxation, expansion, and elasticity* of the fibres; all which are but different ways of expressing the various modifications and dispositions of these machines, whereof all the fibres are composed.

Thus much being granted of the construction of a fibre, and the qualities for its office, it is to be considered, how it comes first to be set in motion, and by what mechanism that motion is afterwards carried on. Suppose then the fibre (fig. 8.) in such a state of distention, as before mentioned; it is certain by fig. 2. that in all parts there is a *series repulsa*; where, then, any external impulse is made against it from R to S, successively, thrusting it from P towards Q, it is certain that against T, for instance, the thrust will be more distended than in any other parts; and thus there will be a greater endosmotic relaxation; and therefore the impulse passing on towards S, all the constituent machinulae, 1, 2, 3, 4, will successively move one after another.

To make this matter still more plain, let a portion of an artery be represented by fig. 9. through which the blood is continually propelled in a direction parallel to its axis; nothing is more certain than that it is not for the resistance of the sides of the artery at E, F, the blood being cut at A, B, would go on by the prickled lines C, D; and therefore it cannot but strike against the sides of the artery at E, F, and distract them there more than any where else; whereby their endosmotic relaxation will be there the greatest; and therefore, when the impulse of the blood has raised them to a certain measure, wherein their endosmotic relaxation will exceed the impulse which raised or distracted them, their contractile powers will draw them again into the same dimensions; and consequently the blood will be thrust forward into the next section of the artery, and so on successively from one to another, through the whole course of its circulation; the contraction of one section of an artery being the true cause of the blood's impulse against, and raising the next. See *MORLEY* and *MALCOLM MORRISON*.

FIBRE is also applied, in *Physiologia*, to those long, fine parts, or threads, whereof other natural bodies are composed, and which prevent their being friable or brittle.

Trees, plants, and fruits, have their fibres, or capillaments; which are modifications of their woody substance, permeating and terminating in the parenchyma, or pulp.

In the common sense, fibre is chiefly applied to the denser capillary parts of plants.

Kerkelevius gives fibre to the fibres, and explains several of their motions from the situation of their fibres.

FIBRILLA, a little fibre, or capillary.

FIBRE SILENTES, those which consist wholly of small fibres, such as the roots of the meadow-grass plants, and several other flowers. When a fibre or root penetrates straight into the ground, it is called *perennans*; when it creeps under the surface horizontally, when somewhat thick, it is called *capillaris*; when very thin, *capillaria*; when it runs sinuously undulated, *serpens*; when divided, or when it splits off smaller roots, *branchata*; when its surface is covered with extremely short and fine fibres, *lucida*. See *Root*.

FIBRILLA, in *Anatomy* one of the bones of the leg, called also *perone, fibula, and osseus minimus*. See *Tab. Anat. (Fibula)*, fig. 3. h. 24. fig. 7. n. 27, 27.

The *fibula* is the outer and slenderer of the two bones of the leg; and yet, notwithstanding its being more expanded, and its being much weaker, than the inner bone, or tibia, it is not so often broken, as being more pliant and flexible; whence the tibia often breaks, leaving the *fibula* entire.

The *fibula* is joined or articulated with the tibia, at both ends. It is divided into three parts. The upper extremity of this bone is a kind of tuberosity or head, obliquely flatted by a small cartilaginous plane, by which it is articulated with the cartilaginous surface, or the lower part of the external condyle of the tibia. It terminates backward by a kind of short blunt point slightly upward. The lower extremity is broader, biter, and more oblong than the upper; it is partly a continuation of the body of the bones, and partly an epiphysis in children; the marks of which are quite lost in a more advanced age. It has in a manner three sides, one round like a cuber, say, one flat, and the third narrow; when it is placed in the lateral cavity of the basin of the tibia, it makes the outer angle opposite to the inner angle.

In its natural situation, it reaches much lower down than the bulb of the tibia, and ends in a point named a little backward. The flat side is cartilaginous, and turned toward the cartilaginous side of the upper ankle, with which, and with the inferior side of the tibia, it completely forms the cavity by which the leg is articulated with the foot. The narrow side is turned backward, and near its lower part is a small, oblong, unequal fella, formerly believed to be for the passage of a tendon, in which a small mucilaginous gland is lodged. The point by which the bulb of the *fibula* ends, has a small smooth surface immediately below the narrow side, for the insertion of an annular ligament.

The body of this bone is long and small, more or less compressed, and irregularly triangular. Near the two extremities it contracts into a kind of neck, and a little below the middle it is often bent inward; but this curvature seems chiefly owing to the method of dissection; for we sometimes meet with the bone very straight, less distinguished in an irregular manner into three sides, and three angles, principally towards its lower part. The outside is the most considerable; the upper part of it is more or less hollowed; afterwards it grows round, and altering its direction, becomes almost perpendicular to the lower bulb. The posterior side is more or less convex toward the upper part, thence it grows flat, and turning in the same manner as the former, it becomes nearly internal toward the lower part. The inner side has likewise a turn near its middle, and becomes anterior from thence downward; and this turn is marked by an oblique line, which runs down on this side, front behind, forward, and divides it into two. These sides serve partly for muscles to be upon, and partly for their insertions. The internal angle of the *fibula* answers to the external posterior angle of the tibia, and both serve for the insertion of the interosseous ligament of the leg; the other two angles are more or less acute, especially the anterior, which is sometimes like a kind of crista, and terminates below in a small triangular surface.

The internal structure of the *fibula*, though a very small bone, is like that of the other long bones; it is articulated by its upper extremity, with the inferior surface of the external condyle of the tibia; this articulation is an anarthrosis, with a very small degree of motion. The inferior extremity is articulated by its cartilaginous side, partly with the lateral depression in the basin of the tibia and partly with the first bone of the foot, completing the ginglymus between the leg and that bone. *Winflow's Anatomy*, p. 95.

FIBRILLA, cartilage of leg. The *fibula* has two cartilages, one lying on the upper extremity of that bone, for its articulation with the small cartilaginous surface in the basin of the tibia; the other cartilage covers the inside of the inferior extremity, or the outer side, near the point of which, posteriorly, there is a superficial cartilaginous incrustation for the passage of the vessels of the muscular peroneal. The cartilage at the upper extremity seems thicker than at the lower. *Winflow's Anatomy*, p. 123.

FIBRILLA, ligaments of leg. This bone is joined to the tibia by nine ligaments, four at each end, and one in the middle, called the interosseous ligament. The four at the upper extremity are short, very strong, more or less oblique and compound; two of them are anterior and two posterior, and they lie on each other; the superior ligament surrounding the articulation more closely than the inferior which have a small round space, and are weaker than the former; they are all fastened to the capsular ligament, which runs in between them and the articulation, and they are inserted round the edges of the cartilaginous surfaces in each bone.

of *Flora*, *Campus Flava*, in Rome; and the *Field of May*, *Campus Martii*, among our ancestors, &c.

FIELD of Mars was denominated from a temple of that deity, built therein; it was the scene, or place, of the assemblies called *comitia*. Tarquin the Proud at length appropriated it to his own use; but after the expulsion of the kings, the consuls Brutus and Collatinus restored it to the public use again, for assemblies and elections. Originally it was no more than a meadow on the banks of the Tiber, where horses grazed, and the Roman youth were exercised to war. But it was afterwards erected into a magnificent square, adorned with statues, &c. See *CAMPUS Martius*.

FIELD of Flava, was the place where the laws, edicts, and constitutions, were published.

FIELD of May, see *CAMPUS Martii*.

FIELD *huffi*, in Botany. See *CLINOPEDIUM*.

FIELD *huffi*, American. See *MONARDA*.

FIELD *huffi*, Syrian. See *BASIL*.

FIELD, *chiff*, was anciently a place enclosed, or railed in with a barrier, for julls and tournaments to be performed in.

FIELD, *Elifian*. See *ELYSIAN*.

FIELD *fort*. See *FIELD FORT*.

FIELD *works*, in Fortification, are those thrown up by an army, in the besieging of a fortress; or else by the besieged, in defence of that place. Such are the fortifications of camps, highways, &c.

FIELD, in Heraldry, is the surface, or face of the shield, or escutcheon: thus called, as containing the achievements anciently acquired in the field of battle.

The *field* is the ground whereon the colours, bearings, metals, furs, charges, &c. are represented. In blazoning a coat, we always begin with the *field*: he bears sable, &c.

Among the more modern heralds, *field* is less frequently used than shield, or escutcheon.

FIELD *colours*, in the Military Art, are small flags about a foot and a half square, which are carried along with the quarter-master-general for marking out the ground for the several squadrons and battalions of an army. They are placed on the right and left of the parade of a regiment when in the field; they are of the same colour with the facing of the regiment, and have the number of the regiment upon them. See *FLAG*.

FIELD-marshal is the denomination of a modern military rank in England, but superior to all others; having the chief command of the whole army.

FIELD *officers*. See *OFFICERS*.

FIELD-fare, in Ornithology, the English name of a bird of the thrush kind, called by authors *turdus pilaris*. It is larger than the common thrush, and is of a bluish grey colour on the neck; the head is spotted with black, and the shoulders and back are of a yellowish brown, variegated with black; the throat is variegated with black and yellow, the lower part of the belly is white, and but a little spotted; and on each side of the neck, and near each eye, it has a large black spot; those on the neck are on its lower part near the insertions of the wings; its wing-feathers are variegated with black, white, and a yellowish brown, and the tail is of a bluish black, with some variegations of black and white; the legs are black, and the talons very strong. These birds generally weigh about four ounces; their length is ten inches, and their breadth six or seven.

It is a bird of passage, and visits us in England toward the end of autumn in vast flocks, and leaves us in spring; it is not certainly known where they breed. They feed on berries, particularly those of the holly, and are a well liked bird.

This bird is easily taken with water bird-line in the following manner: take out a gun, and kill two or three *field-fares* with it; by that time the gun has been discharged two or three times, the rest of these birds will be so shy, that there will be no coming near them; then tie one or two of those that were shot to the upper branches of a bushy tree, in such manner, that they may seem alive and sitting there. Then prepare two or three hundred fitts, covering them well with the water bird-line, made warm for that purpose; take a good birchen bough, and in that place all the twigs; tie this fitt to the tree, just underneath where the other *field-fares* are tied, and let this be in a place where they come in a morning to feed, for they always use one haunt for feeding so long as there is any food left there. By this means the *field-fares* will settle in whole flocks, near those which they feed to the bush; and two or three dozen may be in this manner taken at a time. See *BIRD* and *LINE*.

FIELD of a painting, &c. is more usually called the *GROUND* thereof.

FIELD-pieces are small cannon, usually carried along with an

army in the *fields*: such as one, one and a half, two, three, six, nine, and twelve pounders; which being light and small, are easily carried.

The small pieces differ in length and weight: the dimensions of the others are exhibited in the following table.

Brass field-pieces.

Caliber.	Length.	Weight.
Pect.	inch.	C. Q. lb.
12	5 0 8	3 2
6	4 6 4	3 10
3	3 6 2	2 10

See *CARRIAGE and GUN*.

FIELD-staff, is a staff carried by the gunners, in which they sciew lighted matches, when they are on command; which is called *arming the field-staff*. See *LIGHTSTOCK*.

FIELD of vision, in Optics, is that conical space indefinitely extended before us, so as to include all objects that can be seen at one view, or without turning the eyes. The precise limits of this space are not easily ascertained. In looking at a small distance, we have an imperfect glimpse of objects through almost the extent of a hemisphere, or at least for above sixty degrees each way from the optic axis; but towards the extremity of this space, objects are very imperfectly seen; and the diameter of the field of distinct vision does not subtend an angle of more than five degrees at most; so that the diameter of a distinct image on the retina is less than $\frac{1}{30}$ of an inch; but it is probably much less. See *VISION*.

FIELD-book, in Surveying, a book used for setting down angles, distances, and other things, remarkable in taking surveys.

The pages of the *field-book* may be conveniently divided into five columns. In the middle column the angles at the several stations taken by the theodolite are to be entered, with the distances from the junction. The distances taken by the offset staff, on either side of the station line, are to be entered into the columns on either side of the middle column, according to their position with respect to that line. The names or characters of the objects, with proper remarks, may be entered in the columns on either side of these last mentioned.

FIELD, in War, the place where a battle was fought. The general remained master of the field of battle.

FIERI *factum*, in Law, a judicial writ, which lies at all times within the year and day, for him that hath recovered in an action of debt and damages: it is directed to the sheriff, commanding him to levy the debt and damages on him, against whom the recovery was had.

FIFE, in Music, a sort of wind instrument, being a small pipe.

FIFE-major. See *MAJOR*.

FIRE-raids, in a Ship, are those that are placed on banisters on each side of the top of the poop, and to along with *banister* or *falls*. They reach down to the quarter-deck, and to the stern of the gangway.

FIFTEENTH, *Dactus quintus*, or *Quinquagesimus*, an ancient tribute, or imposition of money, laid upon any city, borough, or other town, through the realm; not by the pope, or upon this or that man, but in general upon the whole city, or town.

It is so called, because it was supposed to amount to a fifteenth part of that which the city hath been valued at of old; or to a fifteenth part of every man's personal estate, according to a reasonable valuation.

This was imposed by parliament, and every town through the realm knew what a *fifteenth* for themselves amounted to, because it was always the same; whereas the subsidy, which was raised of every particular man's lands, or goods, might needs be uncertain.

The *fifteenth* seems to have been a rate anciently laid upon every town, according to the land, or circuit belonging to it. Camden mentions many of these *fifteenth* in his Britain, viz. p. 171. *Ecce redibant pro viginti bidis, quatuordecim siliis graminis, &c.* And p. 181. *Old Sax was pro quinquagesimo bidis redibant, &c.* Which taxes are according to Doomsday. But in after-times the *fifteenth* came to be understood as imposed only on goods and chattels, not on lands. It was first granted by parliament, 18 Edw. 1. viz. *Comptur quintus decimus regi, ac 18. per archiepiscopos, episcopos, abbatas, priores, conventus, barones, & omnes alios ad regem, de omnibus bonis mobilibus concessis.* The city of London paid that year for the *fifteenth* 2860l. 13s. 8d. and the abbot of St. Edmund's 666l. 13s. 4d. which was by composition; and thereupon had all the temporal goods of their district discharged of the *fifteenth*.

In the 8th of Edw. III. it was reduced to a certainty, when, by virtue of the king's committal new taxation, were made of every township, borough, and city, in the kingdom, and recorded in the exchequer; which rate was, at the time, the *fourth* part of the value of every township, and the whole amounted to about 20,000*l*.

The way of collecting it was by two assessors appointed in every county by the king, who appointed twelve more in every hundred to make a true valuation of every man's personal estate upon which the *fourth* part was levied. FIFTH, in *Mus*, one of the harmonical intervals, or concords.

The *five* is the third, in order, of the concords. The ratio of the chords that produce it, is 3 : 2. It is called *five*, because it contains five terms, or sounds, between its extremes, and four degrees; so that in the natural scale of music it comes in the *five* place, or order, from the fundamental.

The ancients called this interval *diapente*. The *imperfect*, or *defective five*, by the ancients called *quintadecima*, is less than the *five*, by a mean *semitone*.

FIG-*tree*, *Ficus*, in *Botany*, a genus of the *pentagynae*, or *gynae* class. Its characters are these: it has male and female flowers included within the skin of the fruit, so that they do not appear, unless the covering be opened; the male flowers are but few in number and are situated in the upper part of the fruit; the female flowers are numerous, and situated in the lower part. The male flower sits each upon a separate foot-stalk, and have no petals, but three bristly stamens; the female flowers sit upon distinct foot-stalks; they have no petals but a green, which afterward becomes a large seed, fitting in the empanculation. There are eleven species; some of which are cultivated in the gardens of England, but many more in those of France and Italy, where the fruit is in very high esteem; as it is also with the nice palates here, though to much out of favour with the vulgar, that it stands safe on trees planted in places where every other species of fruit would be stripped by robbers.

One great discouragement to their more frequent propagation in England, is the unskillfulness of the generality of our gardeners in their culture and management. To obviate which, it may not be amiss to say somewhat at large here, of the proper management of all the species of this tree.

The common method has been to propagate these trees by suckers from the roots of the old ones, but they are much more successfully raised from cuttings. These should be taken from the trees in autumn, and chosen from such branches as are compact, with their joints near each other: they should have a part of the former year's wood at their bottom, and the top of each should be left entire. They then should be planted, eight or nine inches deep, in a bed of loamy earth, warmly situated; the surface of the ground should be covered with old tanner's bark, three or four inches thick, and in severe frost their tops should be covered with straw, &c. which should be removed in the spring, but the rim should be suffered to remain. In the following autumn, they will be fit to remove. This is the proper season to transplant them; and the best soil is such as has a gravelly, chalky, or limy bottom, with a light surface; the tree will seem to flourish indeed more in a better soil, but in this poor one it will produce the thickest and most plentiful fruit. They should always be planted in a free open situation, not shaded by trees or buildings, and will never ripen their fruit well, unless against a good south, south-east, or south-west wall. They should be planted at twenty feet distance, and the height for the wall they stand against is about fourteen feet; the middle space between the trees may be planted with vines to fill up the vacant part of the wall till the *figs* are grown, and then these should be taken up. In the summer, as the branches shoot, they must be trained horizontally against the walls and no forsight shoots should be suffered to come, but the buds of such should be rubbed off as fast as they appear. At Michaelmas they should be always pruned and nailed up. The great care to be had in pruning the old trees, is always to have a supply of young branches for their only produce fruit. None of the shoots of the former autumn pruning must be shortened; for it is on the two year old wood, that the fruit is produced; the young branches must be always brought very close to the wall, and this will prevent them from injuries by frosts, and much forward the early ripening of their fruit. The old branches should never be laid too thick, which is a great fault among most gardeners; the distance ought to be at least a foot between branch and branch; and as the young ones grow strong, the old ones should be always cut away. In April, or the beginning of May, several of the leading shoots should be stopped, which makes them throw out side-branches. In autumn the

tree may be loosened from the walls, and the branches may be laid down and tied to stakes, so as to keep them from the damp ground; and thus in very hard weather be covered with straw, pease-husks, or the like; and that not to be removed till the weather is milder, and then not all at once, but only by a little at a time. In mild weather the covering should be removed; or else the *figs* will come out too early, and be damaged by the cold of April and May. In the spring, when the *figs* begin to push out, the trees may be fastened to the wall again. The higher the wood runs up the wall, usually in such the better suited to the fruit; and no tree succeeds better in fruiting than those which are nailed up against chimneys, where, beside the height, they have some advantage from the heat.

Fig-trees are always planted as standards in warm countries; but in England they are generally planted against walls; however, since some of the varieties are found to ripen their fruit well upon the standards, and the crop of *figs* is often greater upon them than on the trees that are planted against walls, it is a desirable object to plant them either in standards or espaliers. The latter will be the most likely to succeed, if they are managed as in Germany, where they once the *fig-tree* from the espalier, and lay them down, covering them in winter with straw or litter, and this covering is gradually removed in the spring. They should not be fastened up again till the end of March.

The principal and most valuable varieties of the common sort of *fig* are the brown or chestnut-coloured *figs*, the black *Genoa figs*, the small white early *figs*, the large white *Genoa figs*, the black *figs*, the *Malta figs*, the *Murrey* or *brown Naples figs*, the green *figs*, the *Madona figs*, commonly called here the *Brunk-wick* or *Hanover figs*, the common blue or purple *figs*, the long brown *Naples figs*, the yellow *figs*, the small brown *figs*, and the *Genoa figs*. The first, second, third, ninth, and tenth sorts, will ripen their fruits on standards, in a warm situation; but the others require the assistance of walls exposed to good aspects, otherwise their fruit will not ripen in England. Miller.

Figs contain a great quantity of plegm, a little volatile, alkali salt, and a moderate quantity of oil. They are moderately nourishing, grateful to the stomach, easier of digestion than any of the other *fig* fruits and soften the asperities of the breath, &c. and accordingly are used in medicine, to make purgatives against disorders of the throat and mouth; and as an ingredient in pectoral decoctions, and in nutritive electuaries. They are also applied externally, to sores, ulcers, and promote maturation.

Figs are dried either by a furnace, or in the sun, having first dipped them in scalding hot ley, made of the ashes of the *fig-tree*. The Latins call them *varice*, or *figs*, when thus dried.

In this condition they are used both as medicine and food; being both the wholsome, and easier of digestion, when thus cleared of a quantity of their aqueous and viscid parts.

The best *figs* are the produce of Turkey, Italy, Spain, Provence, &c. The islands of the Archipelago yield *figs* in great abundance; but they are much inferior in goodness to those of Europe. Yet the Greeks in those islands cultivate them with wonderful care and attention; as making the principal food, and a considerable part of the riches of the country.

They have two kinds of *fig-trees*; the first called *stans*, or the *wild fig-tree*; the second, the *domestic fig-tree*.

The method of cultivating and ripening these *figs* makes a peculiar art, by the ancients called *epistemon*, often spoken of among them in terms of admiration. Some of the modern naturalists have looked on it as a chimera; but M. de la Hire has assured us of the contrary, and given us that process, as he learnt it upon the spot. See CAPRIFICATION.

The generation of the *fig* is somewhat anomalous; the parts subservient to the office in other plants, i. e. the flower, not being here apparent. But the anatomy of the fruit helps us out of the difficulty.

M. de la Hire the younger, in the Memoirs of the French Academy, shews, that the *fig* is a flower, as well as a fruit. By dissection, it discovers all the essentials of a flower, viz. stamens, apices, and fruit locumens.

The common dried *figs* afford two very curious phenomena; the one is, that within those which are somewhat decayed, and indeed often in those which appear most sound, there are a peculiar sort of mites, which live on the pulp of the fruit, and we eat millions of them unknowingly in this fruit.

These are different from the common mites, in that they are rounder bodied and more transparent, and are very beautiful little creatures when examined.

The other object is the feed, in which the plantula feminis is very elegantly to be seen. For this purpose the largest fig must be chosen, for the smaller are commonly such as are pulled off the tree before they are ripe. Out of one of these large and ripe figs a fair feed is to be selected; and on cutting this carefully, the whole pulpy part may be separated from the hard shaft; and on examining it, there will be found lodged in it a very perfect and beautiful little plant, consisting of two leaves, and of a part which is to be the root, and another which is to be the stalk, and is near the trunk of the tree. The pulpy matter of this feed is covered with a delicate thin membrane, and this must be carefully taken off, before the plantula can be seen. After this, all the rest is only a sort of pulp, destined to give place and nourishment to the young shoot, before it is committed to the soil.

FIGURE cloth of Graham's, in the South Sea, is a coarse and harsh cloth, of the colour of the darkest brown paper, made of the bark of a tree which resembles the wild fig-tree of the West Indies. This cloth has the quality of resisting waters, and the greatest part of it is performed, and worn by the chiefs as a morning dress. For the method of manufacturing and colouring this cloth, see *AROUTA*. Haverfield's *Voyage*, vol. ii. p. 232, See.

FIG, in *alchemy*, were said in divination. See *SECO-MARTIA*.

FIG, in the *Myths*, is a sort of war on the fruits, and sometimes all over the body of a horse. The fig that appears in the fruit or sole, make an evacuation of stinking malign humours, that are very hard to cure.

FIG, in *India*, in *Botany*. See *PRICKLY PEAR*.

FIG, in *astronomy*. See *MESEMBRYANTHEMUM*.

FIG, in *Pliny's*. See *PLANTAGINE*.

FIG, in *Natural History*, is a name given by the English to the creature called by the French, after Mr. Reaumur, the *fine coccine*, or *fine puceron*, from its very much resembling the puceron in external appearance, but being extremely different from it when nearly examined. These insects are, when in their full growth, of the figure of the head of a pin of the largest size, but there are usually found among them several that are smaller, down to such as are scarce perceptible to the naked eye. They are found in great plenty on the back, or under side of the leaves of the *fig-tree*, but they never are seen in clusters like the puceron.

The body and breast of this insect are green, and the sides of the wings are white, and beset with hairs. This creature has two antennae or horns, which it can exert at pleasure; but they usually are lodged under the furrows of the wings, and are not to be seen, unless the animal be turned belly upwards; the head also is bent downwards, and the eyes seem directed to look at objects only placed under them.

It has six legs, and a fine small trunk issuing from the extremity of the head; this is but figure, and is of a lively green; it is terminated by a sharp point, and has a fine brown filament like a hair, which it twirls out of the body of the trunk at pleasure, and which forms a sort of engine or organ destined to convey into the body the juices extravasated by the wound and suction of the trunk. The creature usually remains in perfect quietude on the leaf on which it is found; but has this peculiarity in its position, that it is always found with its head raised upon one of the ribs of the leaf, and its body on the plain parts by this means the anterior part of the head is raised above the surface of the plain part of the leaf, and the creature can by that advantage move his trunk about at pleasure, and fix it into different parts of the leaf, while his body is perfectly still at the time.

These creatures throw off their skins many times in their growth, the furrows marking the places where their wings are, and the protuberances made by their cales are always in, however young they are examined.

In the months of May and June these insects all become winged, and afford a prodigious species of a four-winged fly, which is remarkable for hopping; but as its hind legs are not nearly larger than the rest, it leaps but in a slow way at a time. The body of this fly is green, its wings are bordered with yellow, and its legs are white; it has a trunk of the same nature with that of the creature before its winged state, and with this it continues to suck the juices of the leaves of the *fig-tree* as it did before.

The manner in which these animals propagate their species is not yet known. The progeny, to which they more approach in figure than to any other animals, have always a young one found within them; but thick, if examined in whatever time, never have any such appearance, nor even so much as eggs being found in them; it should seem that their eggs are too minute for our inspection, but that they are oviparous, not viviparous animals. Reaumur's *Hist.* vol. vi. p. 99.

FIG, in *Botany*. See *DOCK*.

FIG, in *Botany*, *Scitellaria*, a genus of the *dicotyledonae angiospermæ* class. Its characters are these: the flower has a permanent calyx, and not five parts in the top; it has one unequal petal, which is large globular, tubercle the lobes in cutting five small parts; the two upper large and crack, the lower ones spread open, and the under ones reflexed; it hath four tender distinct stamens, two of which are the length of the petal, and two shorter, reclined by ten filaments; and an oval germina supporting a single style, crowned by a single stigma; the ovary is situated near to a roundish pointed capsule, with two seeds, which open at the top, and are filled with small seeds. Linnæus reckons fifteen and Moler eighteen species.

The root and leaves of *Scitellaria* have been observed externally as a remedy for the phlegm, inflammation, lamphus, tumours, and cold ulcers. It is generally made into an ointment for these purposes; but some give it also internally in diet drinks. At present they are both among us discredited.

This root is of a very singular figure, by which it is easily distinguished at sight from all other medicinal roots. It is usually of the thickness of a man's finger, or more, of an oblong figure, nearly as thick at the one end as the other, and full of protuberances on the surface, resembling a kind of little kerucly and between these there are a great many fibres which strike deep into the ground. The root itself has no great smell, but its taste is somewhat acid and disagreeable.

FIG, in *Natural History*, the name of an insect, which feeds on the leaves of the *fig-tree*, or *fig-leaf*, and which is usually esteemed a caterpillar, but is one of those insects called by the French *saute saute*.

FIG, in *astronomy*. See *PLANTAGINE*.

FIG, in *astronomy*, are the walls of which hang round about her in a night, to hinder the men from being seen by the enemy.

FIG, in *astronomy*, denote those bell-shaped clouds that the ship which are put up for men to stand secure behind, and fire on the enemy, in case of boarding. See *CLOUD*.

FIG, in *astronomy*, are the walls of which hang round about her in a night, to hinder the men from being seen by the enemy.

FIG, in *astronomy*, are the walls of which hang round about her in a night, to hinder the men from being seen by the enemy.

FIG, in *astronomy*, are the walls of which hang round about her in a night, to hinder the men from being seen by the enemy.

FIG, in *astronomy*, are the walls of which hang round about her in a night, to hinder the men from being seen by the enemy.

FIG, in *astronomy*, are the walls of which hang round about her in a night, to hinder the men from being seen by the enemy.

FIG, in *astronomy*, are the walls of which hang round about her in a night, to hinder the men from being seen by the enemy.

FIG, in *astronomy*, are the walls of which hang round about her in a night, to hinder the men from being seen by the enemy.

FIG, in *astronomy*, are the walls of which hang round about her in a night, to hinder the men from being seen by the enemy.

FIG, in *astronomy*, are the walls of which hang round about her in a night, to hinder the men from being seen by the enemy.

FIG, in *astronomy*, are the walls of which hang round about her in a night, to hinder the men from being seen by the enemy.

FIG, in *astronomy*, are the walls of which hang round about her in a night, to hinder the men from being seen by the enemy.

FIG, in *astronomy*, are the walls of which hang round about her in a night, to hinder the men from being seen by the enemy.

FIG, in *astronomy*, are the walls of which hang round about her in a night, to hinder the men from being seen by the enemy.

FIG, in *astronomy*, are the walls of which hang round about her in a night, to hinder the men from being seen by the enemy.

the *figure*, bulk, and motions of the atoms, or primary corporeities of bodies.

For the *figure* of bodies, considered as objects of sight, see *VISION*.

The *figure* of a figure, whether or no the quality of *figure* be the same with that of *form*, & if they differ, what it is that constitutes the difference? Boethius will have *figure* only pronounced of inanimate bodies, and *form* of animate. Others extend *figure* to all natural things, and *form* to all artificial ones; whence the verse,

Formam viventi, pluri est figuram.

Others apply *figure* indifferently to all kinds of bodies, but not in all relations. If only the bare circumference, or circumscription, be considered, they call it *figure*; but if the circumference be considered as endowed with colour, they then call it *color*.

FIGURES, in *Architecture* and *Statuary*, denote representations of things made in solid matters; such as statues, &c.

We say, *figures* of brail, of marble, of stucco, of plaster, &c.

But, in this sense too, the term is more usually applied to human representations than to other things. Thus we say, an equestrian *figure*, for a man on horseback.

David observes, that those either represented things, as paper, &c. or kneeling, as on monuments, &c. or laid all along as rivers, &c. are more properly called *figures* than statues.

FIGURES, in *Architecture*, are said to be detached, when they stand singly, in opposition to those compositions which are called *ensembles*.

FIGURES, in *Arithmetic*, are the numeral characters, or the characters whereby numbers are expressed, or written. Thus the number of four hundred and fifty is written, or expressed, by these *figures* 450.

The *figures* in arithmetic are the nine digits; 1, 2, 3, 4, 5, 6, 7, 8, 9, and 0.

The *figures* were first brought into Europe by the Moors of Spain, and into England, in Dr. Wallis's apprehension, about 1550. See *ARITHMETIC* and *CHARACTER*.

However, from some ancient dates, supposed to consist wholly or in part of Arabian *figures*, some have concluded, that these *figures*, originally Indian, were known and used in this country at least as early as the tenth century. The most ancient date discovered by Dr. Wallis was that on a chimney piece, at Helmdon, in Northamptonshire, M. 1133, i. e. 1133. Other dates discovered since, are 1000, at Colchester, in Essex, 1010, with the Roman M for a thousand, at Wiggle-Hall, near Huntingdon, in Hertfordshire, 1011 on the north front of the parish church of Ramsey in Hampshire, and 975 over a gate way at Worcester. Dr. Ward has urged several objections against the antiquity of these dates. As no example occurs of the use of these *figures* in any ancient manuscript, earlier than some copies of Johannes de Sacro Bologno, who died in 1256, he thinks it strange, that workmen should have made use of the *figures* so long before they appear in the writings of the learned; and he also disputes the fact. The Helmdon date, according to him, should be 1233; the Colchester date 1490; that at Wiggle-Hall has in it no Arabian *figures*, the 1 and 6 being, I think, the initial letters of a name; and the date at Worcester, he supposes to consist of Roman numerals; and to be really MXXV. Mariyn's *Algebra* of Phil. Trans. vol. 1. p. 420, &c.

FIGURE, in *Astronomy*, a description, or draught, of the state and disposition of the heavens, at a certain hour, containing the places of the planets and stars, marked down in a *figure* of twelve triangles, called *houses*.

This is also called a *horoscope* and *triangulum*.

FIGURE, in *Astronomy*, denotes a representation of the path or orbit of the sun, and the moon, during the time of an eclipse, upon paper; with the number of digits eclipsed, and the beginnings, middle, and end, of darkness.

FIGURE of the *summer*. The rectangle under any diameter, and its proper parameters, is in the ellipse and hyperbola called the *figure* of half diameter.

FIGURE, or *Division*, of the full moon, such as viewed through a telescope with two convex glasses, is of considerable use in observations of eclipses, and conjunctions of the moon with other luminaries. In this *figure* of the moon are represented the nucleus, or spots, of the moon, marked by numbers; beginning with the spots, which usually enter first within the shade at the time of the great eclipse, and also denote the first.

FIGURE, in *Conics* denotes the rectangle, made under the latus rectum and transverse, in the hyperbola and ellipse.

FIGURE, in *Dancing*, denote the several steps which the dancers make in order, and cadence, considered as they mark certain *figures* on the floor.

FIGURES, in *Fencing*, are the direct guards, postures, situations or dispositions, of the body, arms, or sword. See *FENCING*.

FIGURE, in *Geometry*, is the plan of any solidified space;

or the interior part of a body, &c.

When the *base* and *apex* are equal, it is called a *regular* (or when unequal, an *irregular* *figure*).

FIGURE, in *Geometry*, is applied to the extremes of points, lines, or numbers, thousand, or cast at random, on the combinations or variations whereof the *figure* of this art found their methodical directions.

FIGURE, in *Geometry*, denotes a surface included, or comprehended with one or more lines.

Such are triangles, squares, polygons, circles, ellipses, &c.

Wallis defines *figure* a continuum terminated by a perimetre. In which sense *figure* is applicable both to superficies and solids. In the former case, the perimetre is of lines; in the second, of surfaces.

Figures are either rectilinear, curvilinear, or mixt, according as the perimetre consists of right lines, curve lines, or both.

The superficial parts of a *figure* are called its *face*; the lowest side, its *base*; and the angle opposite to the base, the *vertex*.

The height of a *figure* is the distance of the vertex from the base.

FIGURE, in *Grammar*, is an expression that deviates from the common and natural rules of grammar: either for the sake of elegance or brevity.

The best grammarians only reckon four *figures*; the *ELIPTIC*, *PERSONAL*, *SYLLEPTIC*, and *HYPERBOLICAL*. Others add two more, viz. *ANAPHORICAL*, and *CHACOTICAL*.

FIGURE, in *Heraldry*, a bearing in a shield. Of these *figures* there is almost an infinite variety; some are natural, such as the celestial *figures* of the sun, moon, stars, &c. and their parts; the signs of men, women, &c. and their parts; animals as lions, dogs, horses, bears, &c. and their parts; birds, as eagles, swans, flocks, peacocks, &c. and their parts; fishes, or dolphins, whales, porpoises, trout, &c. and their parts; reptiles, and insects, as tortoises, serpents, grasshoppers, &c. and their parts; vegetables, as trees, plants, flowers, berries, &c. and their parts; and things, as diamonds, rubies, pebbles, rocks, &c. These charges, as well as ordinaries, have divers attributes or epithets, which express their qualities, positions, and disposition. Thus, the sun is said to be in his *glory*, *alighted*, &c. the moon is her *complement*, *invergent*, &c. Animals are said to be *passant*, *passant*, *passant*, &c. Birds have also their denominations; a feline is described to be *heraldic*, *heraldic*, &c. Besides these natural *figures*, there are also artificial *figures*; the principal of which are warlike instruments, as swords, arrows, battering rams, pavises, helmets, spears, pole-axes, ornaments used in royal and religious ceremonies, as crowns, coronets, mitres, wreaths, croziers, scepters, castles, arches, columns, plumes, battlements, churches, posterns, borrowed from architecture and fortification; and ships, anchors, rudders, pendulous sails, oars, masts, flags, galleys, lighters, &c. derived from navigation; all these bearings have different epithets, denoting their position, structure, &c.

There are likewise chimerical or imaginary *figures* used in heraldry, that are the result of fancy and caprice; such as centaurs, hydra, phoenixes, griffins, dragons, &c. Pomey's *Elem. Herald.* p. 129, &c. 132, &c.

FIGURE, in *Logic*, denotes a certain disposition of the terms of a syllogism; particularly of the medium, with regard to the extremes.

Hence it follows, that there are as many *figures* of syllogisms, as there are different combinations of the extremes with the medium; so that, though the logicians ordinarily only reckon three, yet a fourth might be admitted.

In the *first figure* the medium or middle term is the subject of both the propositions, and the predicate of the minor. This contains four moods, and applies to the proof of all sorts of questions, whether universal or particular, affirmative or negative. In the *second figure* the middle term is the predicate of both the premises, and this contains four moods, admitting only of negative conclusions.

The *third figure* requires that the middle term be the subject of both the premises, and has six moods, admitting only of particular conclusions. The special rules of these three *figures* are the following: in the *first*, the major proposition must always be universal, and the minor affirmative; in the second also the major must be universal, and one of the premises, together with the conclusion, must be negative; in the *third figure* the minor must be affirmative, and the conclusion always particular.

FIGURED, in the *Manufactures*. A *figured* SAMLET, stuff, tabby, &c. is that wherein there are divers designs of flowers, figures, branches, &c. imparted by means of hot irons.

FIGURED ribbands first came into fashion about the year 1680. The method of performance was by successively applying steel plates engraved with divers ornaments, as flowers, birds, grotesques, &c.

But one Chandler, a ribband-maker of Paris, invented a much better and readier way of doing it, by a machine but unlike the latter used in coining to flatten the pieces of metal, only much simpler.

The principal parts thereof were two steel cylinders, engraved with the figures intended to be represented. These cylinders were placed over each other like the rolls of a rolling-press, having each of them, at one of its extremes a little dent which, one of which catching into the other, the whole was put in motion by means of a winch or handle fastened to the first.

The machine thus prepared, the workman heats the cylinders, and places the ribband in the little place remaining between the two, which he contracts yet farther by a screw that presses the upper part down upon the lower; then turning the rolls by the handle, a whole piece of RIBBAND was figured in less time than a single yard could be done in the ordinary way.

FIGURED velvet. See VELVET.

FILAGEOUS, in *Botany*, a term applied to such roots of plants as are full of filaments. See FILAMENT.

FILACIUM. See FILL.

FILAGO, in *Botany*. There are several species of this genus, some of which grow naturally on barren land in moist parts of England. They are called by some cotton-wood; by others cud-wood, their leaves being white; and when broken, appearing to consist of cottony threads. Most botanists have ranged them under the genus of *cyathodium*. See CYATHODIUM. Linnaeus makes the *Filago* a distinct genus of the *symplocaria palustris* near *farcta* class, with a naked receptacle, no down, an imbricated calyx, and small female flowers placed between the folds of the calyx.

FILAMENT, in *Medicine*, *Antiquary*, *Natural History*, &c. a term used in the same sense with *thread* for those fine threads wherewith flesh, nerves, skins, plants, roots, &c. are composed.

FILANDERS, in *Falconry*, a disease in hawks, &c. consisting of filaments or strings of blood coagulated and dried, occasioned by a violent rupture of some vein, by which the blood extravasating, hardens into the figures above mentioned, to the great annoyance of the reins, hips, &c.

The word is French, *filander*, formed from *fil*, thread.

FILANDERS are also a sort of fine small worms which greatly incommode the hawk in the gorge, and about the heart, liver, and lungs; but which, on some occasions, are supposed to be of service, and to feed on the superfluities of certain parts. See BACK-ROCK.

There are four kinds of these *filanders* or *vermin*. The first, in the gorge or throat; the second, in the belly; the third, in the reins; the fourth, the *filander* is called *medicines*, on account of their exceeding fineness. The symptoms that discover the disease are the bird's going frequently straining the filth or perch with her pounce, crouching in the night, rolling her train, rubbing her eyes, wings, nostrils, &c. As the worms are very restless, the bird is frequently endeavouring to cast them up; and in opening its mouth, you will readily discover them. From the throat, &c. they will ascend to the lungs, brain, &c. and finally over the whole body.

The ordinary cause is bad food. The proper remedy, they say, is not by killing them, for fear of impurities from their corruption; but chiefly by supplying them, that they may be offensive but seldom.

This is best effected by making the bird swallow a clove of garlic, after which will feel nothing of the *filander* for forty days. Others use rue, worm-wood, aloes, retin, saffron, &c.

FILAWS, among the modern Egyptians, villages inhabited by the original natives of the country.

FILAZER, **FILACER**, **FILITZER**, an officer in the court of common-pleas, who called because he *fil* the writs wherewith he makes out process.

Of these there are six in the several divisions and counties of England. They make out all writs and process upon original writs, issuing out of the chancery as well real as personal and mixed, returnable in that court. In actions merely personal, where the defendants are returned summonses, they make out poines or attachments, which being returned and executed, if the defendant appears not, they make out a distringas, and so *ad inhibicionem*, or till he does appear.

If he be returned *non*, then process of capias infinite if

the plaintiff will; or after the third capias the plaintiff may proceed to outlawry in the county where his original is grounded, and may have an exigent with proclamation.

The *filazers* likewise make out all writs of view in real actions where the view is prayed; and upon replevin and *recofrans*, writs of *retorno habendo*, second deliverance, and writs of *wherewith*. In real actions they make out writs of grand and petit capias before appearance.

They enter all appearances and special bail upon any process made by them. They make the first fine facias upon special bail, writs of habeas corpus, *distingas* super *vicecomitem* vel *balium*, and *places* return; and all *in personam*, upon special bail or appearance, &c. writs of habeas corpus cum causa upon the sheriff's return that the defendant is detained with other persons, and writs of adjournment of a term, in case of pestilence, war, or public disturbance.

Till an order of court made 12 Jan. 1, which limited the *filazers* to all matters and proceedings before appearance, and the prothonotaries to all after, they also entered declarations, impanelments, judgments, and pleas, whereto a *serjeant's* hand was not requisite, and made out writs of execution and divers other judicial writs after appearance.

FILBERDS, or **FILBERS**, the best sort of small nuts, proper for planting in orchards or gardens.

They are raised from nuts set in the earth, or sockets from the roots of an old tree, or they may be grafted on the common *stake*—*nut*.

They delight in a fine mellow, light ground, but will grow almost anywhere, especially in defended from violent and cold winds.

The tree is easily propagated, bears well, and is of two sorts, the *white* and the *red*, but the former is the best.

FIL, an instrument of steel, cut in late hatches or furrows, used by the workmen in metals, to smooth, polish, and otherwise fashion the same.

The word is French, *fil*, literally signifying a long series or succession of any kind of things, of *fil*, thread.

Filer bear a near resemblance to *rasps*, the only difference between them is, that the former are cut with edged tools, and the latter are punched with pointed ones. See RASP.

The *fil* is a principal instrument in all the kinds and parts of smithery. It should be forged of the best steel, after which, robbing it with grease, to make it more soft under the chisel, they cut it with chisels and a mallet, this and that way, and of this or that depth, according to the grain or tooth required.

After cutting the *fil*, it remains to be tempered; which, being the principal mystery of making the *fil*, will deserve to be particularly described.

Fils then are tempered with a composition of chimney-soot, very dry and hard, diluted and worked up with urine and vinegar, to which is added common salt: the whole is to be reduced to the consistence of mud.

The *fil* being cut, and rubbed over with vinegar and salt to free it from oil the grease laid on for the cutting, they cover them over with this composition; and having laid several of them together in a basket, and covered them in loam, they put them in a furnace fire, from which they are taken out again by that time they have acquired a cherry-colour, which is known by a little red rod of the same steel put in along with them. Upon taking them out, they cast them into the coldest spring water they can get.

Iron *fils* require a more intense heat than steel ones. When the *fils* are cold they clean them with charcoal, a rag, &c. to take away any of the soot or scales left in the cutting; then drying them before the fire, they put them up carefully in a box of wheat bran, to keep them from rusting.

Fils are of different forms, according to the different uses and occasions they are made for. Those in common use are the square, flat, triangular, half-round, round, thin *fil*, &c. all which are made of different sizes, as well as different cuts and degrees of fineness, to take place according as the work is more or less advanced, some cutting faster, as the *rough-cut* *fil*, &c. others more slowly, as the *finished* *fil*, &c.

Fil is also a thread of wire wherein wires or other exhibits in courts or offices are fastened or filed, for the more safe keeping and ready turning to the same.

A *fil* is a record of the court, and the filing of the process of a suit makes a record of it.

FIL, or **label**, in *Heraldry*, a bearing represented in *Tab. Herald* fig. 23. though instances of more, and sometimes of fewer points, being the difference or distinction of the eldest son.

It is sometimes also borne in a charge, in a coat-armour, of which Gualtier gives many instances; but it is often the difference or mark of distinction which the elder brother

ther brass in his coat during his father's life.

Some distinguish *fil* and *label*, calling the *fil* the upper horizontal line, and the *label* the points which issue from it.

FILE of three, or more, *labels*. See **LABEL**.

FILE, in a *Military Sense*, is a row of men standing one behind or below another from front to rear.

Or, *fil* is a line or series of soldiers, placed one before another, and thus composing the *DEPTH* of a battalion or squadron. The *fil* which bind the right and left are called the *flanks*.

They say, *close the files*, that is, bring the men nearer each other. *Double the files*; that is, double the depth of the battalion, and diminish its breadth or front by one half. The last or hindmost person is said to *bring up the file*. To *file off*, is to wheel off from marching in a spacious front, and to march in length by *files*.

FILE-MAJORS, are the foremost men in each *file*.

FILE-MAJORS, *halls*, are the men of the fourth rank; the fourth, fifth, and sixth ranks being called the *rear half-fil*, the *fil*, as the first, second, and third are the *front half-fil*.

FILIAL, something belonging to the relation of a son.

The stones usually distinguished between a *servile* and a *filial* fear. The most abandoned have a *servile* fear of God, such as that of a slave to his master; but not a *filial* fear, i. e. a fear inspring from love and respect.

FILICOLA, in *Botany*. See **Dwarf-FERN**.

FILIGRANE, or **FILIGRANE**, is a kind of enrichment on gold or silver, wrought delicately in manner of little wheels or grains, or both intermixed. The word is compounded of *fil* or *filum*, thread, and *granum*, grain.

In Latin it is called *filum elaboratum auri, argenti, cuprum*.

We have *vases*, &c. of *filigree* work. The term has been lately applied, to ornamental works, formed, as fancy directs, of strips of paper, dexterly coloured, rolled into various figures, and artfully combined.

FILING, one of the principal operations in smithery, &c. succeeding to forging.

The coarser cut files are always to be succeeded by finer; and in all the kinds the rule is to lean heavily on the file in shuffling it forward, because the teeth of the file are made to cut forwards; but in drawing the file back again for a second stroke, it is to be lightly lifted just above the work, because it cuts not coming back.

The rough or coarse-toothed file (which, when large, is called a *rubber*) serves to take off the unevenness of the work left by the hammer in forging.

The half-toothed file is to take out the too deep cuts and file-strokes made by the rough file; the fine-toothed file takes out the cuts or file-strokes the ballard-file made; and lastly, the smooth file those left by the fine file.

In this order the files of several cuts are to succeed each other till the work is as smooth as it can be filed; after which it may be made yet smoother with emery, tripoli, &c. See **POLISHING**.

FILIPENDULA, in *Botany*. See **DROGWORT** and **SRI-RAN**.

FILIUS ante patrem, q. d. the son before the father, a denomination applied by botanists and florists to plants whose flowers come out before their leaves. Such are the several species of colchicum or meadow-saffron, the colts-foot, buttercup, &c.

FILIX, in *Botany*. See **FERN**.

FI VILLA, in the *Sicilian* language, is to brace the sails in such a manner, that the wind entering their cavities from behind, dilates them, so as to advance the ship in her course, after the sails had been for some time fluttering or braced back.

FILLAR, or **PHILLIS**, *Herf.* See **THILLER**.

FILLET, in *Antiquity*. See **FRANKUM**.

The word is French, *fil*, formed of *fil*, thread.

FILLET, or **FILLET**, in *Architecture*, denotes a little square member or ornament used in divers places and on divers occasions, but generally as a sort of cornice over a greater moulding. See *Tab. Archit. fig. 2. N. 1.*

The *fil* is the same with what the French call *reglet*, *bande*, and *banderole*; the Italian, *fillo*, or *listello*.

FILLET, in *Botany. See **THYRSUS**.*

FILLET, *twisted*, in *Horology*, a kind of orle or border, containing only a third or fourth part of the breadth of the common *border*.

It is supposed to be withdrawn inwards, and is of a different colour from the field. It runs quite round, near the edge, as a lace over a cloak.

FILLET is also used for an ordinary drawn like the bar from the snail's point of the chief across the shield, in manner of a fess; though it is sometimes also seen in the situation of a bend, fesse, cross, &c.

According to Guillim, the *fil* is a fourth part of the chief, and is placed in the chief point of the cincture.

FILLET is also used among *Painters*, *Gilders*, &c. for a

little rule and sort of leaf-gold, drawn over certain mouldings; or on the edges of frames, panels, &c. especially when painted white, by way of enrichment.

FILLETS, in the *Mane*, are the joints of a horse, which begin at the place where the hinder-part of the field is rectified.

FILLY, a term among *Horse-dealers*, to denote the female or mare colt. See **FOAL**.

FILM, a thick skin or pellicle.

In plants it is often used for that thin woody skin which separates the seeds in the pods, and keeps them apart.

FILM, *white*, on the eye of a horse, may be removed by lifting up the eyelid, after the eye has been washed with wine, and stroking it gently with the thumb with wheat-flour, common salt and salt of lead, beaten fine, and put into the eye, are proper to consume a *film*; or the horse's eye may be washed with the spittle in the morning, filling, having first put a little salt into your mouth; but there is nothing so effectual as sal ammoniac, beaten and put into the eye, and repeated every day till the *film* is gone.

FILTER, or **FILTER**, in *Chemistry*, &c. a piece of woollen cloth, linen, paper, or other matter, some of which are in the form of hollow inverted cones, used to filtrate or strain liquors through.

The *filter* has the same use and effect with regard to liquids that the *seive* or *searce* has in dry matters.

Filters are of two sorts: the first are simple pieces of paper or cloth, through which the liquid is passed without further trouble.

The second are twisted up like a skin or wick, and first wetted, then liquor put in, and one end put in the vessel that contains the liquor to be filtrated; the other end is to be cut, and hang down below the surface of the liquor; by means hereof the purest part of the liquor distils drop by drop out of the vessel, leaving the coarser part behind. This *filter* or *filter* acts as a siphon.

FILTER is also a charm, supposed to have a virtue of inspiring love.

The word is derived from *sortum*, which signifies the same thing, of *sortes*, and *sortum*.

The Greeks, when their love was without success, had several arts to procure the affection of their beloved. The Thessalian women were famous for their skill in this, as well as other magical practices. The means whereby it was effected were of divers sorts: it was sometimes done by potions, called *sortes*, which are frequently mentioned in authors of both languages. Juvenal speaks thus:

*His magis efficit potus, hic Thessala vinctis
Philtre, quoniam vultus mœstem vœrang morit.*

Their operations are violent and dangerous, and commonly deprived of success as drunk men of their reason. Plutarch and Cornelius Nepos report, that Lucullus, the Roman general, first lost his reason, and afterwards his life by one of them. Lucretius, the poet, ended his life by the same way; and Caius Cælius, as Suetonius reports, was driven into a fit of madness by a *philtre* given him by his wife Calpurnia, which fillet is mentioned by the same poet. Ovid likewise allures us, that this was the usual effect of such potions.

The ingredients they were made of were of divers sorts, several of which, applied by themselves, were thought effectual.

FILTRATION, the act of passing any liquor through a *filter*, called also *culinary*, *percolation*, and *transcolation*. See **FILTAL**.

The end of *filtration* is of two kinds; the one to free fluids from any solid bodies of a feculent nature with which they are mixed; and the other to separate any precipitated powder, or other solid body from a superfluous fluid, and the means must be varied accordingly. Such liquors as are incorporated with particles that adhere to them are rendered capable of *filtration* by coagulating and collecting the heterogeneous parts. This is effected either by boiling or by mixing whites of eggs and beating them with the turbid liquors. See **CLARIFICATION**.

The most commodious way of *filtration* is by whitened paper fastened over the mouth or aperture of a funnel; the smallness of the pores of this paper admits only the finer parts through, and keeps the rest behind. There are also *filtrations* through sand, pulverized glass, &c. Spirits of vitriol, salt, and nitre, are *filtrated* through a quantity of beaten glass in the bottom of a funnel.

Filtration is also performed by a woollen or linen bag, called Hippocrates's Sleeve: the choice of these must be directed by the liquor to be *filtrated*.

Dr. Papin contrived a method by which *filtrations* through cap-paper might be made suddenly, and with great quantities of liquor, by the help of the air-pump. For this purpose he made use of the following contrivance: A A (*Tab. II. Hydrostatica*, See *fig. 9.*) is a glass receiver,

ceizer, BB a cover fitted to it, CCC is a pipe forming the communication between the receiver AA and the air-pump, DD a shallow vessel full of little holes, EEE a pipe that makes the communication between the vessel DD and the receiver AA, FF a vessel to contain the liquor to be filtrated, and GG the plate of the pump. When this instrument is used, the shallow vessel DD ought to be tied about first with linen cloth, and then with cap-paper, so that no liquor may get into the holes of the said vessel but through the cap-paper, and linen cloth; this must be wholly placed within the liquor to be filtrated: let the air be extracted by means of the air-pump out of the vessel AA. Then the liquor in the vessel FF must be drawn through the cap-paper, and the linen cloth into the vessel DD, and from thence through the pipe EEE into the vessel AA; and this operation must be quick, on account of the great pressure of the atmosphere that drives the liquor; besides, the sediment of the liquor subsiding at the bottom of the vessel FF will not be so apt to stop the pores of the cap-paper as in ordinary filtrations. Birch's Hist. of the Royal Society, vol. IV. p. 366, 367.

The secretion of the divers juices in the body from the mass of blood seems to be little else but filtration. Pitcairns, and other late authors, hold that the diversity of filtrations does not depend on the different configurations of pores, but on their different faces or diameters. Springs, also, seem to be raised from the ocean by the same principle of filtration.

FILTRATION, in Pharmacy, is chiefly concerned in tinctures; as when some portion is drawn from the ingredients or suspended in the tincture which is not necessary thereto, but disturbs and renders the rest unpleasant both to the palate and sight. Beside this, there is a filtration which has much tortured the philosophy of some ages to account for; this is that performed by the ascent of the finer parts of a liquor up a cord or skin of cotton, or such like matter, which is contrived to drop over another vessel and leave the grosser behind.

After the same manner is, without doubt, that the humidity of the earth is drawn up into the substance of the roots of vegetables, which we know consist of long and very minute fibres, so disposed as to form a great number of tubular interstices; these act in the nature of this sort of filter, and attract the juices and moisture appointed for the nutriment and increase of the plant.

Some say, that the cause of this ascent is because the liquor itself seeks those parts of the filter that touch it, by entering into the pores of the threads which compose it, whereby they rise up, touch, and wet those next above them; and chase again the next threads, and so on to the brim of the vessel, when the liquor runs over, and descends in the other part of the filter which hangs down by its own natural gravity.

But this account is liable to many objections, especially as liquors rise after the like manner in glass tubes much above the surface of the liquor they are immersed in, where the glass cannot be imagined thus to swell. Others account for it by considering every filter as composed of a great number of long, small, solid bodies, which lie very close together; so that the air getting in between them loses much of its pressure, and cannot gravitate so strongly as it doth on the fluid without them; the consequence is, that the parts of the water between the threads of the filter must be pressed upwards, and ascend till they come so high, as, by their weight, to counterbalance the general pressure on the other parts of the surface of the water.

Lastly, the retainers to Sir Isaac Newton's philosophy deduce the phenomenon from the principle of attraction. According to them, the cause of this filtration is, doubtless, the same with that whereby fluids ascend up heaps of ashes, sand, &c. the same with that whereby water is raised in flood of vapour, the sap rises in vegetables, and the blood circulates through the capillary arteries, and the extremely minute glandular excretors. See ASCENT of fluids.

FILTRUM, in Natural History, the name of a stone much in use in the eastern parts of the world, and sometimes with us for the filtering of water intended for drinking. The Japanese are extremely fond of this stone, and impute their uninterrupted health, and particularly their being always free from the stone and gravel to their drinking the water thus cleared of all its heterogeneous and mischievous particles. The people of this, and many other places thereabouts, have a settled opinion, that most diseases arise from impurities of water, and are well assured, that these impurities are all lodged in the stone-filter, and left behind by the water in its passage. The manner of using the stone is this; they form a sort of mazers with very thick bottoms out of the largest pieces of it, and the water is poured into these, and the

stone being of a very lax and spongy texture, it soon makes its way through, and is received into a vessel placed underneath for that purpose. If being found, therefore, an easy thing for us to have our water filtered in the same manner that the Japanese have, it remains to try whether it will have all those salutary effects which the people of that part of the world give it, and this seems not to be imagined from reason and analogy. We very well know, that water is frequently impregnated with saline particles, and that it also frequently dissolves by this means earthy and other matters which in other ways could not do. But we also know, that salts dissolved in water are not to be separated by filtration, and it is equally certain, that earthy, starchy, or other matter, that is suspended in water when clear, will in like manner pass through the filter with it.

Upon the whole, we are happy enough to have no occasion for filtering stones, since our springs and rivers afford us water as ready pure enough to our hands; and in places where this is not the case, it is always possible to raise rain-water, which will keep a long time with proper management, and is much purer than all the rest in the world can make such as has once been foul. Valentinus Muscum Matorcum, lib. I. c. 2. p. 52.

The only instance in which a filtering-stone can be of real use, is, when there is no water to be had but that of some muddy river; in this case, the mud being a foreign body not dissolved in, but only floating among the water, it will be left behind in passing the cloth. If otherwise in the filter; but this is always to be as well obtained by letting it stand a while to subside. Ephemer. Germ. Cent. III. p. 76.

FILUM Aquæ, the thread or middle of the stream where a river parts two lordships: *Est hoc fluvius fluvii, ut quædam fluvium aquæ præstat. Filum nam, the high side of the sea.* Rot. Parl. 11 Hen. IV.

FIMBRIÆ, in Geometry, the extremities or borders of the tube Fallopiæ were formerly thus called, the word signifying a fringed border, which that part resembles. See Tab. Anat. (Splanchn.) fig. 10. d. d.

FIMBRIATED, a term in Heraldry, signifying that an ordinary is edged round with another of a different colour.

Thus, the beareth, or, a cross-patee gules, *fimbriated* sable.

FIN, in Natural History, the name of that part of a fish, which distinguishes it from other aquatic creatures, no animal but a fish having fin and wanting legs.

The fin is properly a part standing out or hanging from the body of the fish, and consisting of a membrane supported by several rays or osseous bones, which are in some hard and firm, and in others cartilaginous.

This definition of a fin properly excludes all those other parts of a fish which may be prominent from the body, and may be of a membranaceous structure, and even bear the appearance of a fin, though they have none of the rays or little bony substance within them, and therefore cannot serve the creature in the office of fin in swimming; for the cartilages or bones which support the membranes of the fin are what give them their due and necessary strength and firmness to bear against the water for the motion of the body of the fish; those other membranaceous appendages to the bodies of fishes cannot do this; for wanting the support of these rays, the simple and soft membrane has no more power of moving the water than the water has of moving it. Hence appears the use of the bones or rays supporting the fin, and the truth of the definition, that nothing is properly a fin which wants them.

The fin, by their differences, make very obvious distinctions among the several species of fish, and their differences are in regard to number, situation, figure, and proportion.

The number of the fin, including the tail, is very different in different fish. 1. In some there is only one fin to the whole fish: this is the case in the opidium lumbiciforme, and in the murena. 2. The fin is two in number in others, as in the petromyzon, and the like. 3. There are many which have three fin, as the roger, the eel, the common opidium, the Greenland whale, the sea-row, and the like. 4. Many have four fin; of the number of which are the dolphin, the phocaena, and the second kind of the sea Arctureus. 5. Several have five fin, as the annulatus or sand-rel, the sword-fish, the lupus marinus, the mola or tun-fish, and many others. 6. The lampfish gives us an instance of six fin; for the swimming fin is on the back of this fish is not a real fin, but only a curious prominence. 7. Many fish have seven fin, as the guayfish, the pleuroctes, the cyprinus, the clupea, the cyprone, the eimeri, the salmon, the cobitis, the clupea, the cerania fluvialis, the gasterosteus, the spina, the labia, the fish-

rus, the mugil alatus, the temera, the capricorn, the hipparus, the pompius, and the accipenser. 8. Many fish also have eight *fin* each; of this number are some of the perches, the clares, the cotus, the mugil, the labrus, the fustis, the mulu, the ling, the trachurus, the sericeus, the trachinus, the *sermoteope*, and that little fish called the anguilla by the Veterinarius. 9. The poem of Rondeletius gives us an instance of the *fin* being nine in number; and finally, the *combri* and *thynn* give us instances of eleven *fin* in the same fish.

The differences in situation are less numerous than these as to number, but they are not less obvious and essential. 1. They are generally placed both on the back and belly, as we see in most of the species of fishes. 2. They are sometimes placed only on the back; this is the case in the *peromyza*, the *scot lumbiciformis*, and some others. 3. Some have them, on the contrary, only on the belly; of this kind are the Greenland whale, the *sea-eel*, and the like: and to this it is to be added, that the back and belly *fin* differ greatly in the several fish, in their being placed more or less backward or forward.

The differences of shape or figure in the *fin* of fishes are also very obvious. 1. They are in some nearly triangular, as in the cyprin, and salmon, &c. 2. Some few fish have them round. And 3. Some have them of an oblong square or parallelogram figure. Finally, the difference in proportion is not to be omitted, for they are in some much shorter and smaller than the body, as is the case in the generality of fish; but in others they are of an equal length with the body. Of this kind are the pedonal *fin* in some of the *legions*, and the ventral *fin* in the mugil *sturi* of Rondeletius and other authors. Arted, Ichthyol. p. 4.

FIN-FISH, the *salmo physalis* of Linnaeus, is a species of WHALE, distinguished from the common whale by a *fin* on the back, placed very low and near the tail.

The office of the *fin* has commonly been supposed to be analogous to that of feathers in fowls, and to assist the fish in its progressive motion or swimming; but the latter naturalists find this a mistake.

It is the tail that is the greatest instrument of swimming; the *fin* only serve to keep the fish upright, and prevent vacillation or wavering. See SWIMMING in fish.

FINN, *whale*, are commonly taken for that part of the whale which the populace call *WHALE-TOOTH*; but whence the mistake should arise is not easy to determine.

These *whale-fins*, as some have erroneously called them, are the most valuable part of the animal. See WHOLE FISHERY and WHALE-TOOTH.

FINAL, that which terminates or comes last in any thing, as a final judgment, final sentence, &c.

FINAL CASE, is the end for which the thing is done. The final *cause* is the first thing in the intention of a person who does a thing; and the last, in the execution. See CAUSE.

FINAL LETTERS are those which close words.

The Hebrews have five final letters, which, when at the end of a word have a different figure from what they have at the beginning or in the middle thereof. These are the *א, ב, ג, ד, ה*, which *א, ב, ג, ד, ה*, which every where but at the end of words, are wrote *א, ב, ג, ד, ה*.

FINANCES, in the French Policy, denote the revenues of the king and states; much the same with the treasury or exchequer of the English, and the *finances* of the Romans. The word is derived from the German, *finnen*, *frängen*, *wheren*, though Du-Cange chooses rather to deduce it from the barbarous Latin, *financia*, *frangitio pecuniarum*.

FINANCES, *council* of the, corresponds to our lord commissioners of the treasury; the comptroller general of the *finances*, to our lord high treasurer, &c.

The French have a peculiar kind of figures or numeral characters, which they call *chiffres de finances*. See CIPHER.

FINANCES, BRITISH. See FUND.

FINCH, in Ornithology. See FRINGILLA.

FINDERS, in our Old Statute, are supposed to be the same with those we now call searchers, who are employed for the discovery of goods imported or exported without paying custom. Stat. 13 Ed. III. c. 11. Ric. II. c. 17. Ric. II. c. 17.

FINDING, among Sportsmen. See WIRE-DOG.

FINDING of a bill of indictment in Law. See INDICTMENT.

FINE, that which is pure, and without mixture. The term is particularly used in speaking of gold or silver. See GOLD and SILVER.

FINE, in Law, denotes a covenant made before justice, and entered on record, for conveyance of lands, tenements, or any thing inheritable, being *in esse tempore finis* in order to cut off all future controversies.

A *fine*, then, appears to be a concord, a knowledge and recorded before a competent judge, touching some

hereditament or thing immovable that was in controversy between the parties to it in some concord; and for the better credit of the transaction, it is supposed to be made in the presence of the king, because levied in his court.

Hence it binds women covert, being parties, and obliges whom ordinarily the law disables to testify, only for this reason, that all presumption of deceit or evil-meaning is excluded where the king and his court of justice are supposed to be privy to the act.

Originally this *fine* concord was instituted and allowed, in regard that by the law and ancient course of proceedings, no plaintiff could agree or end the cause without licence of the court; so that *fine* have been anciently levied in personal actions, and for no greater a sum of money than 11s.

But time has produced other uses of *fine*, viz. to cut off entails, bar dowers, and with more certainty to pass the interest or title of any land or tenement, though not converted, to whom we think good, either for years or in fee, inasmuch that the paying a *fine* in real causes now is but a *voluntaria*, depending on action or controversy, where, in truth, none is, and to act only operating as a present bar and satisfaction against the cognitor or person who passes the *fine*, and his heirs but at five years end, against all others, not expressly excepted, and not claiming (if it be levied upon good consideration, and without collusion) as women covert, persons under twenty-one years, prisoners, or such as are out of the realm at the time of its acknowledging; and persons *non sane mentis*, who are allowed the same time after their malady is removed.

To this purpose a *fine* after the engrossing must be openly read and proclaimed in the court of common pleas, once in the term when they were engrossed, and once in each of the three succeeding terms, and a transcript of it sent to the justices of assize, and another to the justices of the peace of the county where the land lies, to be proclaimed there. The day and year of acknowledging a *fine* and warrant of attorney for suffering a recovery are to be certified with the consent, and an office hath been appointed for the enrolment of writs for *fine*; and the liographer, on the fifth day of every term, is to fix in the court of C. B. or common pleas, a table containing the *fine* passed in the term before in every county, by stat. Eliz. cap. 3.

Every *fine* hath in it five essential parts: 1. An original writ, usually a writ of covenant. 2. The king's licence, giving the parties liberty to accord; for which he hath a *fine* called the *single*, *quere*, being accounted part of the crown revenue. 3. The concord itself, which begins thus, *Et est concordia facta*, &c. 4. The note or abstract of the *fine*, beginning thus, *Ita est concordia*, &c. 5. *Et T. nostrum qui deferuntur*, &c. (where instead of *deferuntur*, anciently *impeduntur* was used.) 6. The foot of the *fine* (*Hec est finis concordia facta in curia domini regis apud West. a die Pasche in quinquagesima anno*, &c.) concludes all, containing the day, year, and place, and before what justice the concord was made.

Fines are either with proclamation, called *fine* according to the statutes, which are the best sort, and most used; or without proclamation, called *fine* at the common law.

Fines are either *single* or *double*.

FINE, SINGLE, is that by which nothing is granted or rendered back again by the cognitors to the cognisors, or any of them.

FINE, DOUBLE, contains a grant and render-back, either of some rent, common, or other thing out of the lands, or of the land itself, to all or some of the cognisors for some estate, binding thereby remainders to strangers not named in the writ of covenant.

In this kind of *fine* called *fine* *per se*, grant and render, both the *fine* *per cognitores*, &c. and *per cognitores*, are formed into one; and it is partly executed and partly executory.

Sometimes also a *double fine* is when the lands lie in several counties.

Fines, with regard to their effect, are divided into *executory* and *executed*.

FINE, EXECUTORY, is such as of its own force gives a present possession (at least in law) to a cognitor; so that he needs no writ of *habere facias possessionem* for execution of the same, of which sort is a *fine* *per cognitores de terra sua*, &c. that is, upon acknowledgement, that the thing mentioned in the concord is *in sua possessione*, *et de qua terra facta est concordia*, &c. Well, 3 s. 1. K.

The reason is, because the *fine* passes by way of release of a thing which the cognitor hath already (at least by supposition) by virtue of a former gift to the cognitor, which is, in truth, the fourth use of all.

FINE, EXECUTORY, are such as of their own force do not execute

cute or give the possession to the cognisee without entry or action, but require a writ of *habere faciet possessionem*, as a *fine* for cognisance de droit tantum, unless the party be in possession of the lands. This kind of *fine* is commonly made use of to pass a reversion. There is also another executory *fine*, called for *conveyance*, which is used to grant away estate for life or years, when the cognisor is seized of the lands contained therein, and the cognisee hath no freehold in it, but a patent by the *fine*.

Fines in England are now levied in the court of common pleas at Westminster, in regard to the solemnity thereof, ordained by the statute of 18 Ed. I. stat. 4. before which time they were sometimes levied in the county-court, court barons, and in the exchequer, as may be seen in *Origines Juridicales*, &c.

Fines are also taken by commissioners in the country, empowered by *delinquis passiones*. 15 Ed. II. stat. de *fine*. Though by the common law all *fin* were levied in the court. *Fines* levied before the Justices in Wales, or in the counties palatine of Cheshire, Durham, &c. have the same effect as those that are levied before the justices of C. B. Plowden says, that there were *fin* levied before the Conqueror: Fullbeck assures us also, that he has seen the exemplification of one of Henry the First's time; though Dugdale affirms, there were none till Henry the Second.

Fine annullans levato de tenemento quod fuit de antiquo dominio, a writ directed to the justices of C. B. for annulling a *fine* levied of lands in ancient demesne to the prejudice of the lord. Reg. Orig. 15.

Fines for alienation, are reasonable *fin* formerly paid to the king by his tenants in chief, for licence to alienate their lands; according to the statute 1 Edw. III. cap. 12. but taken away by statute 13 Car. II. cap. 24.

Fine capiendi pro terris, &c. a writ lying where a person upon conviction of any offence by jury hath his land and goods taken into the king's hands, and his body is committed to prison, to be remitted his imprisonment, and have his lands and goods re-delivered him on obtaining favour for a sum of money. Reg. Orig. 122.

Fine, fines, is an expression in *law*. 35 Hen. VIII. cap. 12. denoting that a person is forced to do that which he can in no way avoid.

Fine levanda de tenemento teniti de rege in capite, &c. a writ directed to the justices of the common pleas to admit of a *fin* for the sale of land holden of the king in *capite*. Reg. Orig. 167.

Fine non capiendi pro pulchre placitando, a writ to inhibit officers of courts to take *fin* for fair pleading. Reg. Orig. 179.

Fine pro redimenda capiendi, &c. a writ lying for the release of one imprisoned for a redhibition, on payment of a reasonable *fine*. Reg. Orig. 222.

Fines le roy, in *law*, are all *fin* to the king. Under this head are included *fin* for original writs. Thus, for every writ of plea of land, if it be not of right patent, which is for the yearly value of five marks, and for all original writs in debt and trespass, where the debt or damage is not a *fine* is due to the king of *his* *sh*; and more proportionably when the writ is for greater value.

Fine also, according to Cowell, signifies a sum of money paid as an income for lands or tenements let by lease, anciently called *persone*.

Fixa is also used to denote an amend, pecuniary punishment, or recompence, for an offence committed against the king and his laws, or against the lord of a manor.

In which case a man is said, *facere finem de transgressione sua*, &c.

In all the diversities of the use of the word *fin*, it hath but one signification; and that is, a *final* conclusion, or end of differences between parties. In the last sense, where it denotes the ending and remission of an offence. It is used by Becketon, who speaks of a *common fin* that the country pays to the king for false judgments or other trespasses, which is to be satisfied by the justices in eyre before their departure, by the oaths of knights and other good men, upon such as ought to pay it.

There is also a *common fin* in courts leet.

Fine-drawing, or *rostering*, a very nice way of sewing up or rejoining the parts of any cloth, stuff, or the like, torn or rent in the dressing, wearing, &c.

It is prohibited to *fine-draw* pieces of foreign manufacture upon those of our own, as has formerly been practised. See *RENTING*.

Fine-diller, in the *Distillery*. That branch of the art which is employed on the distilling the spirit from treacle or other preparations or recrements of sugar, is called *fine-dilling*, by way of distinction from malt-dilling; and the person who exercises this part of the trade is called a *fine-diller*.

The operation in procuring the spirit from sugar is the same with that used in making the malt spirit; a wath of

the saccharine matter being made with water from treacle, &c. and fermented with yeast. It is usual to add in this case, however, a considerable portion of malt, and sometimes powdered jalap, to the fermenting backs. The malt accelerates the fermentation, and makes the spirit come out the cheaper, and the jalap prevents the rise of any mussy head on the surface of the fermenting liquor, so as to leave a greater opportunity for the free access of the air, and thus to shorten the work, by turning the foamy into a hissing fermentation. Shaw's Lect. p. 220.

FINERS of gold and silver, are those who purify and part those metals from other coarser ones by fire and acids.

They are also called *fatters*, in our old law-books, and sometimes *depariers*.

FINERY, in the *Iron-works*, is one of the two forges at which they hammer the low or pig iron.

Into the *finery* they first put the pigs of iron, placing three or four of them, together behind the fire, with a little of one end thrust into it; where, softening by degrees, they stir and work them with long bars of iron, and expose at different times different parts to the blast of the bellows, in order to refine it as equally as possible, till the metal runs together with a round mass or lump, which they call a *half-room*. They then take this out, and give it a few strokes with their sledges; afterwards they carry it to a great heavy hammer, raised by the motion of a water-wheel; where, applying it dexterously to the blows, they presently beat it out into a thick short square. This they put into the *finery* again, and heating it red-hot, they work it out under the same hammer till it comes to be in the shape of a bar in the middle, but with two square knobs at the ends, which they call an *ANCONY*. It is then carried into the other forge, called the *CHAFERY*. Phil. Trans. N° 137, or Abr. vol. II. p. 559.

FINERING. See *VENERING*.

FINESSE, a French term; of late current in English. Literally, it is of no farther import than our English *fineness*; but among us it is chiefly used to denote that peculiar delicacy or subtlety perceived in works of the mind, and the nicest and most correct and sublime parts of any science or art.

It is sometimes used to express that kind of subtlety made use of for the purposes of deception.

FINGERS, *Digiti*, the extreme part of the HAND, divided into five members.

The *fingers* consist of fifteen bones, disposed in three rows or ranks, each *finger* having three bones.

The joints or jointures are called *convexi* and *internodi*, and their arrangement or rows, *phalanges*; the uppermost of which is the longest and largest; the second less, but yet longer and larger than the third.

The first *finger* is called the *pollex* or the *THUMB*; the second, *index*, sometimes *pollicinaris* *digiti*, and sometimes *maritimus*; the third, the middle *finger*, *medius*, *alveolaris*, *indivisus*, and *formosus*, because used in mocking and derision; the fourth, *anularis*, the ring *finger*, *malis* *proximus* and *medius*, because the ancient used to stir and mix their medicines therewith; the fifth, the little *finger*, *auricularis*, because the *ear* is picked therewith.

FINGERS, bones of the. The phalanges of the bones of the four *fingers* are all of nearly the same structure, differing only in size. The first phalanges are made nearly in the same manner with the second of the thumb, only that they are lower on their concave sides, and more rounded at their convex sides. They are also larger in proportion and the edges of the flat sides have the same rough line as the second phalanx of the thumb. Their bases are more hollow for their articulations with the metacarpal bones, and their heads are formed like pulleys. The second phalanges are shorter, narrower, and thinner than the first; both phalanges are gently incurved, and resemble each other in structure, except that the second contract by degrees from their bases to the heads, which are very small, and that their bones have a double cavity for their articulation by ginglymus, with the heads of the first phalanges. Their flat sides have all the before mentioned rough lines. The third phalanges are in every thing like that of the thumb (which see) but that they are smaller, each of them being proportioned to the *fingers* they belong to. It is to be observed of all the phalanges, that their bases have small tuberosities; and their heads, except those of the last phalanges, have on each side a sort of roundish fossula, bordered with small eminences. Winslow's Anatomy, p. 80.

Mr. Huxham has given us observations on the structure and action of some MUSCLES of the *fingers* in the Mem. Acad. Sciences for 1720.

FINGERS, superfluous. Infants are often born with super-

fluos or super-numerary *fingers*, which are usually misshapen and misplaced; some of these are found to have nails and bones like the other fingers; others have none of these, but are mere masses of flesh.

These should always be amputated in the infancy of the child; but if they are many in number, and the child but weakly, it may be better not to take them all off at one time, but to allow some time between each amputation, that one may be amputated before another is taken off. They are to be cut off with the scalpel or scissars, and the hemorrhage stopped with dry lint or with the fume dipped in spirit of wine, and afterwards healed as common wounds with vulnerary balsam. Heister's Surgery, p. 330.

FINGERS, carious. The *fingers* when carious, or affected by a splin venioso, are to be amputated three ways. 1. By a pair of strong scissars or sharp-edged pinchers. 2. By a chisel struck by a leaden mallet, by which they are separated at one blow, or lastly, by dividing the new found joint with a scalpel, and drawing back a part of the skin to wrap over the stump that it may heal the sooner; and that is the best method of all, as by this you are in no fear about any splinters of the bone being left. Heister's Surgery, p. 331.

FINGERS, fractured. When one or more of the bones in the *fingers* are broke, the surgeon's business is carefully to replace what has been removed, and to roll up the *finger* a little way with a narrow bandage, and then to bind it firmly to the next sound *finger*. But it is much more proper, when the *finger* is maimed so as to give no hope of a good cure, to take it off at once. Heister's Surgery, p. 329.

FINGERS, luxated. The bones of the *fingers* and thumbs are liable to luxations of each of their articulations, and that in several directions; but these are accidents, not only easily discovered, but very easily remedied also; for the ligaments being not very robust, the fat and muscles thin, and the funicles of the articulations shallow, the extension is very easy, and the reduction of them into their former places not less so. The best method is to extend sufficiently the *finger* with one hand, and to replace the luxated bone at the same time with the other, and to retain it by a proper bandage. Heister's Surgery, p. 166.

FINGER'S breadth, a measure of two barley-corns in length, or four laid side to side.

FINGERY, in Ichthyology. See BRANLIN.

FINGITES, a name given by some of the barbarous writers of the middle ages to the phlegmities, a very transparent sort of marble used by the Romans in building.

FINGRIGO, Pijonia, in Botany, a genus of the *polygamia distich* class. Its characters are: the male flowers grow upon different plants from the fruit. The male flowers are funnel shaped, the tube is short; the brim is expanded, and cut into five acute points; they have five awl-shaped stamens, which are longer than the petal, terminated by obtuse funiculi: the female flowers are of the same form; they sit upon the germen, which is situated under the receptacle, supporting a cylindrical style longer than the petal, crowned by five oblong spreading stigmas. The germen afterwards turns to an oval capsule, having five angles and one cell, containing one smooth, oblong, oval seed.

We have but one species at present in England, viz. the prickly pisonia, called *figwidge* in the West Indies. These plants are very common in the Lixamas and other low places in the Island of Jamaica; as also in several other Islands in the West Indies, where they are very troublesome to any one who passes through the places of their growth, fastening themselves by their strong crooked thorns to the cloaths of persons; and their seeds being glutinous and burry, also fasten themselves to any thing that touches them; so that the wings of the ground-doves and other birds are often so loaded with the seeds as to prevent their flying, by which means they become an easy prey. Miller.

FINGING, See REFINING.

FIXING of wine. The usual method of *fixing* down wines, so as to render them expeditiously bright, clear, and fit for use, is this: take an ounce of sugar, beat it into thin shreds with a hammer, and dissolve it by boiling in a pint of water; this when cold becomes a stiff jelly. Whisk up some of this jelly into a trough with a little of the wine intended to be fixed, then stir it well among the rest. In the cell, and bung it down tight; by this means the wine will become bright in eight or ten days. This method, however, is found to be best suited to the white wines; for the red ones, the wine coopers commonly use the whites of eggs beat up to a froth, and mixed in the same manner with their wines. The method by which these viscous bodies act in the operation is this; they entangle themselves among the flying lee or light faculties that float in the wine, and thus

forming a mass specifically heavier than the wine, they sink through the body thereof like a net, carrying down all the foulness they meet in the way to the bottom; but when the wine is extremely rich, so that its specific gravity is greater than that of the mass formed by the ingredients used in *fixing* and the dregs or lees this mass then rises upward, and floats at the surface of the wine, which will in this case also draw off fine. See CLARIFICATION and FORCING.

FINIRE, in Lou, was used to *fine*, or pay a fine upon composition and making satisfaction. It is the same with *finir* faces, mentioned in Leg. Hen. I. cap. 53.

FINISHING, in Architecture, &c. is frequently applied to the CROWNING OF ACROTERIA over a piece of building, placed there to terminate and finish it.

FINITE, something bounded or limited, in contradistinction to infinite.

The schoolmen make two kinds of *finite*.

The one is to *terminari*, which is applied to things that have not all possible or conceivable extension.

The other is to *perfectio*, applied to things which have not the last perfection.

To get an idea of a thing *finite* in point of perfection, we first conceive the thing as having certain perfections; and then conceive some other perfection which it has not, or some perfection in a farther degree.

After the same manner I conceive a room to be *finite*, by having an idea of extension beyond what is contained therein.

FINITO, in the Italian Music. A CANTON or VOICE is said to be *finite* when it is not perpetual; but when at some certain places all the parts join or unite, after having followed one another for some time.

FINITOR, in Astronomy, the HORIZON; thus called, because it finishes or bounds the sight or prospect.

FINNIKIN, the name of a particular species of pigeon, called by Moore the *Colomba in gyron fessant*. It is of the shape and size of the common pigeon. The crown of its head has something of the resemblance of a snake's head; and it is gravel-eyed, and has a tuft of feathers on the hinder part of its crown, which runs down its neck not unlike a horse's mane. It is not feather-legged, and is in colour always either a black or blue pied.

They have their name from their singular manner of courting the female, which it always by rising over her, and making three or four turns, flapping the wings, and then turning as many times round the other way.

FINOCHIA, in Gardening, the name of a plant which has of late years been introduced into the English gardens, and cultivated as a salad herb. See FENNEL.

The culture of it is this: good seeds must be first procured from Italy, for those of English ripening are very apt to degenerate. In March some of these should be sowed for the first crop on a light rich earth, and in a warm situation. The manner of sowing these seeds is first to rake the bed very smooth, then draw a small rill along it, and in this scatter them pretty thin, for the plants are not to stand nearer than six inches to one another; cover this with half an inch of earth, and at the distance of eighteen inches make another rill, and so on throughout the bed. In about a month the plants will come up, and they must be then cleared of weeds, and cut up to four inches distance; a month after this they must be thinned to six or seven inches distance; the plants will now begin to swell to a large bulk just above the ground, this part must be earthed up in the manner of celery about a fortnight before it is used, which will make it as very tender and crisp.

A second crop should be sown three weeks after the first, and in that manner till July; every three weeks or month a new crop should be sown, to keep a constant supply for the table. The crops sown in the hotter weather should be watered and shaded from the great heats. Miller.

FINSKALE, an English name for the river fish, more usually called the *salmon*, the *salmon* fish, or *salmon* fish of authors.

FINTO, in the Italian Music, signifies a faint, or an attempt to do something, and not to do it; as *cadenza finita*, is when having done every thing proper for a true cadence, instead of falling on the right final, another note, either higher or lower, is taken, or perhaps a pause brought in.

FIOLA, or FIALA. See PITAL.

FIR-tree, Abies, in Botany, a genus of the *monocladia* class. To this genus Linnaeus refers the pine and Yew trees, making them as well as the *fir-tree* only different species of the *FIRUS*. Its characters are these: there are male and female flowers on the same tree; the male flowers are produced at remote distances from the cones on the same tree; they are composed of many stamens supporting great funiculi, and disposed in a conical spike. The female flowers are collected in a frail cone, each

each scale covering two flowers, having no petals; but from the embryo there arises a single style, covered with a blunt stigma; which embryo afterwards turns to an oblong seed or nut, inclosed between the scales of the cone, each scale having commonly two seeds under it. The distinguishing character of this genus is, that the leaves arise singly from their base, whereas the pines have two or more rising from the same point. There are nine species now in the English gardens. The most common are the silver or yew-leaved *fir-tree* and the pitch-tree, or the Norway spruce *fir*. The first grows in great plenty about Stralburgh and other parts of Germany, from whence the turpentine is brought to England; but the most beautiful of these trees grow on mount Olympus. The second sort is common in the woods of Norway, and affords the white deals. Of this tree there are two or three varieties; from this the pitch is drawn, whence its name. There are two species natives of America, one called the black spruce *fir*, and the other the white spruce *fir*, because the leaves of both are used indifferently for making of *spruce-ber*. These two species also yield a fine clear strong-scented turpentine, which the native Indians use to cure green wounds, and for some internal disorders. The physicians of North America have lately adopted it into their practice. There is another species the native of America, called the balm of Gilead *fir*, because it affords a clear fragrant turpentine, commonly sold in England for the balm of Gilead.

The manner of propagating *fir*, pines, and other trees of that kind from seeds is thus: the ripe cones of these trees are to be either exposed to a gentle heat, or soaked for twelve hours in warm water; after which the several cells will open, and the seeds fall out. These seeds should never be taken out till the time of sowing them, which is the latter end of March. The ground they are to be sown in must be carefully turned several times, to destroy the roots of weeds. For a large plantation, this is best done by ploughing several times; after this, the earth is to be levelled with a spade in small spots at every six feet square, in each of which spots ten or twelve seeds are to be sown, and covered with some of the same mould broken fine, but not sifted; then they are to be covered with a furze bush or other such covering, and this is to remain for some time after the plants are come up, but they must not be covered too close by it; when this covering is taken off, a little loose earth is to be drawn about the stems of the plants, and a little furze fluch about them, to keep off the too great heat of the sun. Usually from twelve seeds there are eight plants or thereabouts, and these may be left standing together till the third year. In March or April, the third year after sowing, the plants are to be removed to the place where they are to stand, and planted at eight foot square distance, or greater, if desired. Two plants should, however, be left in the plantation in each cluster, and great care taken not to injure the roots of these. The others also must be taken up with as much earth about their roots as possible. When they are set in the new plantation, there must be stakes fixed near them to tie them to, that the wind may not blow them down, and the roots must be covered with litter, and they must have a gentle watering to settle the earth to their roots. If the weather prove very dry, this may be repeated two or three times, but a little at a time; over-watering kills all new-set trees; and the cutting away of the heads or branches of those of the resinous kind is a very dangerous thing.

The Scotch pine delights in a chalky soil on the side of a hill, but will also grow in gravel, and in any ground that is not too wet.

The common *fir* loves a lumpy strong soil, and is a native of low fat grounds; and most of the American *fir* and pines love a loose moist soil. The silver *fir*, and the manured pine, love a dry situation, but must have a deeper soil than the Scotch pine, and must be sheltered from the north winds. The two trees left in each spot of the place where they were sown, may be left together seven years, then the least flourishing tree is to be carefully removed. Miller.

Fir, *multi-spicata*. See *Lycopodium*.

Fir, *Scotica*, in Botany. See *Pine*.

FIRDFARE. See *FERRIFARE*.

FIRDWITE. See *FIRDWIT*.

FIRE, in Philosophy. The most universal and sensible character of *fire*, and that which best defines and distinguishes it from every other thing, is, its giving heat.

Fire, therefore, may be generally defined to be whatever warms or heats bodies.

Again, as heat is something whose presence we best perceive by the dilatation of the air, spirit, or mercury in the thermometer; *fire* may be defined to be that whose pre-

sence we perceive by the expansion of these in the thermometer.

Whence it follows, that *fire* is an elastic body, composed of infinitely small particles, scarcely if at all adhering to each other, and a body in motion. Its motion is argued from its expanding the air, which is not effected without communicating motion thereto; and its corporeity is proved by experiment. For pure mercury being included in a glass with a long neck, and kept in a gentle heat for the space of a year, is reduced into a solid; and its weight is considerably increased; which increase, some have supposed, can arise from nothing but the accession of *fire*. See the sequel of this article, and *CALCINATION*.

Its solidity is also evinced by its reflection from burning-glasses; the smallness of its constituent particles by the facility with which it penetrates any body however dense, or separates itself from any such body.

Fire makes one of the vulgar or Peripatetic elements, defined to be hot and dry; or it is that part or ingredient in all bodies which is hot in the highest degree, and dry in an inferior one.

What the school-philosophers add farther, as to the nature of *fire* is, that it is a simple body, as not including any contrariety of qualities; and a body absolutely light, as tending naturally upward; for which reason they hold its natural place to be above all the other elements, between the extremity of our atmosphere and the moon; and the fund of *fire* is supposed to reside in that space, which they call *elementary fire*.

Fire, according to the Cartesian, is an assemblage of the more solid, earthy particles, which, swimming in the rapidly fluid matter of the first element, become vehemently agitated thereby; and by this intense agitation or motion are disposed to give the sensation of heat, light, &c.

Fire, according to Sir Isaac Newton, is a body heated to hot as to emit light especially; for what else, says that philosopher, is red-hot iron, but *fire*? And what else is a *fiery* coal than red-hot wood? By which he supplies, that bodies which are not *fire* may be changed and converted into *fire*.

It is a dispute of some standing among philosophers, whether *fire* be any specific substance, originally distinct from all other; or whether it be of the common matter of other bodies, only under certain peculiar modifications; i. e. whether *fire* be such by its own nature, or by motion? See *HEAT*, under which article the reader will find this controversy more largely stated and explained. See also *Theory of ELASTICITY* and *PNEUMATICS*.

According to some of the latest philosophers, *fire* is a certain substance or body, *sub generis*, originally such, and not producible by any motion or alteration of other bodies.

These authors describe *fire* as a very subtle, moveable, penetrating body, the cause or instrument of *HEAT* and *LIGHT*.

Some of them add, that when *fire* enters the eye in right lines it produces or excites the idea of light, which rectilinear motion they account absolutely necessary to the idea of light.

Whence, to produce heat, and the other effects of *fire*, such rectilinear motion is not required; but on the contrary, an irregular, various motion is fitter to produce the same.

Others dislike the use of the term *fire* as a constituent principle of natural bodies, because in the general application of it heat has also been included; and therefore the term has become ambiguous, and it is necessary to distinguish continually between *fire* in a state of action and inactive or quiescent *fire*. They have therefore, preferred the term *ERIGLOSTION* for denoting one and the same unknown cause of certain well known effects. Vossler's *Exp. and Obs. Sc.* vol. 1. p. 282, &c.

The nature of *fire* is so wonderful and various, that the ancients generally revered it as a god; among the moderns we can scarce name one point in all philosophy of more importance, or one that is less understood.

Fire, in effect, is the universal instrument of all the motion and action in the universe; without *fire* all bodies would become immovable; as in a severe winter we actually see our fluids become solid for want thereof. Without *fire* a man would harden into a statue, and the very air would cohere into a rigid mass.

Fire, then, is the universal cause of all mutation or change; for all mutation is by motion, and all motion by *fire*.

Several authors have laboured to set this grand agent in its full light; and particularly the excellent Boerhaave, in a new course of experiments and lectures especially on the subject, *De igne*. The sum of his doctrine we shall here subjoin.

Fire, then, is distinguished into two kinds; as it is in itself

itself called *elementary fire*; and as it is joined with other bodies, called *calinary fire*.

FIRE, *pure or elementary*, is such as exists in itself, which alone we properly call *fire*, and has lately been denominated absolute *HEAT*.

FIRE, *common or calinary*, is that existing in ignited bodies, or excited by the former in combustible matters, the minute particles whereof joining with those of the pure fire constitute pure flame.

This latter is improperly called *fire*, in regard only a small part of it is real or pure *fire*.

Pure *fire* is such as collected in a burning-glass yields no flame, smoke, ashes, or the like; consequently, in ignited bodies, that which flames, smokes, &c. is not simply *fire*.

The effects, nature, properties, &c. of each shall be considered: 1. *There is elementary fire of itself is imperceptible, and only discovers itself by certain effects which it produces in bodies, which effects are only learnt by observing the changes that arise in those bodies.*

The first effect of *elementary fire* on bodies is heat, which arises wholly from *fire*; and in such manner as that the measure of heat is always the measure of *fire*, and that of *fire* of heat. So the heat is inseparable from *fire*. The second is dilatation in most solid bodies, and rarefaction in all fluids.

That both these are inseparable from heat, is evident from numerous experiments. An iron-rod or bar being heated, increases in all its dimensions; and the more it is so, is further and further heated; upon exposing it to the cold again, it contracts, and returns successively through all the degrees of its dilatation till it arrives at its first bulk, being never two minutes successively of the same magnitude. See *HEAT* and *PYROMETER*.

The like is observed in the heaviest of all bodies, gold, which, when fused, takes up more space than before; so mercury, the heaviest of all fluids, we have known to ascend in a narrow tube over the *fire* to above thirty times its height.

The laws of this expansion are, 1. That the same degree of *fire* rarefies fluids fourfold, and in a greater degree than it does solids. Without this the thermometer would be of no use, since the empty of the tube would then be dilated in the same proportion as the fluid is rarefied.

2. The lighter the fluid, the more it is dilated by *fire*. Thus air, the lightest of all fluids, expands the most, and next after air, spirit of wine. See *THERMOBAR*.

Some substances are capable of a greater dilatation or diminution of their specific gravity than others by *fire*. Thus, certain matters are so much rarefied by even a moderate heat, that they seem to lose all their specific gravity, or become at least specifically lighter than all the surrounding bodies; hence these substances when heated to a certain degree, are raised as bodies would be without gravity. All substances which have this property are called in general volatile substances. See *VOLATILIZATION*. Other bodies are so little dilatable by *fire* relatively to their density, that the greatest heat which can be given them produces almost an insensible diminution of specific gravity. These, being almost unalterable in this respect by *fire*, are called fixed bodies. See *FIXITY*.

The third effect of *fire* on bodies is motion; for *fire*, in warming and dilating bodies, must of necessity move their parts.

In effect, all the motion in nature arises from *fire*, alone; and, taking this away, all things become immovable. Upon the absence of only a certain degree of *fire*, all oils, fats, waters, wines, ale, spirits of wine, vegetables, animals, &c. become hard, rigid, and inert; and the less the degree of *fire*, the looser and more violently is this solidation made.

Hence, if there were the greatest degree of cold, and all *fire* were absolutely taken away, all nature would grow into one concrete body, solid as gold, and hard as a diamond; but upon the application of *fire*, it would recover its former mobility.

Consequently, every diminution of *fire* is attended with a proportionate diminution of motion, and vice versa.

This *fire*, whose effects we have been relating, needs no air or phlogiston to sustain or preserve it. For putting some coils of tin or lead in the exhausted receiver of an air-pump, and applying a burning-glass, so that the vacuum shall fall on the coils, the consequence will be a vehement dilatation of the coils from the center towards the circumference, whereby the receiver will be broken into a thousand pieces; and if a quantity of any essential aromatic oil be poured, in *vacuo*, upon spirit of nitre, there will immediately arise a violent *fire*, to the great danger of the by-standers.

All the above mentioned effects of *elementary fire* may be increased divers ways, viz.

1. By attrition, or a swift agitation or rubbing of one

body against another. This is apparent in solids; a vehement attrition of a flint and steel, every body knows, will produce sparks. So also in fluids, cream, by long churning, to separate the butter, will grow sensibly warm; the barometer renders this effect still more discernible.

In effect, all the heat of an animal, says Boerhaave, is owing to the agitation and attrition of the parts of its juices against each other, and against the sides of the vessels.

The more solid, hard, and elastic, the bodies thus agitated are, the more points of contact they have; the more intense the force whereby they are struck against each other is, the greater is their motion; and the quicker the return of their strokes, and the longer they are continued, the greater is the heat produced.

Thus, a piece of sponge rubbed lightly, and for a little while against another, acquires no sensible heat; but a large heavy piece of iron briskly rubbed against another in a cold season (when bodies are the densest) will presently acquire an intense heat sufficient to *fire* sulphur, gunpowder, or the like.

So a knife wetted briskly on a dry rough stone shall yield sparks of *fire*; but if oil, or any other fatty matter be interposed, no sensible heat shall arise; and the points of two needles rubbed against each other ever so strongly, or so long, will never grow warm, as only touching in a few parts.

In New Holland they produce *fire* with great facility by means of two pieces of dry soft wood; one of which is a stick about eight or nine inches long, and the other is flat; the stick they shape into an obtuse point at one end, and pressing it upon the other, turn it nimbly by holding it between both their hands as we do a chocolate-mill, often shifting their hands up, and then moving them down upon it, to increase the pressure as much as possible. By this method they get *fire* in less than two minutes. Hawke's Voyages, &c. vol. iii. p. 234.

Hence, 1. The globules of the cruet or red blood driven by the force of the heart against each other, or against the sides of the arteries, excite more heat than the globules of the serum, or any other humour in the animal.

Hence, 2. Those parts abounding most with these globules thus agitated, as the heart, liver, and head, will be the hottest of all others; and the denser the blood, *caloris partibus*, the greater the heat, &c. 3. The quicker the contractions of the heart are repeated, the greater will the heat be. For the more probable cause of animal heat, see *ANIMAL HEAT*.

The second manner of increasing the effect of *elemental fire*, is, by throwing a quantity of moist or green vegetables, cut down while full of sap, into a large heap, and pressing them close down, the result of which is, that they grow warm, hot, smoky; and finally, will break out into flame.

The third way is by the mixture of certain cold bodies. Thus, water and spirit of wine first warmed, grow much hotter by the mixture to any of the heavy, aromatic oils, as of cloves, cinnamon, silistria, guaiacum, &c. mixed with spirit of nitre, grow exceedingly hot, and burst forth like volcanoes; and the same may be said of spirit of nitre and steel-slings.

It is possible to produce *fire* and flame by the bare mixture of two cold liquors, in the following manner: take two drams of strong and fresh spirit of nitre prepared with oil of vitriol, and putting it into a clean and dry gallipot, set it under a chimney, then pour to it at once the oil of cloves one dram, there will be immediately produced a loud noise and a considerable flame; and when that is gone, a dry resin is formed in the pot. See *INFLAMMABILITY*.

The like effect may be had from dry bodies. Thus, pure sulphur and steel-slings, well ground, and mixed in equal quantities, with water enough to make them into a dry paste, and laid an hour or two any where, even under ground, will smoke and emit flame, and that with the greater vehemence as it is more strongly pressed down.

The fourth is by *PHOSPHORUS*, which is a kind of fire-mineral prepared from the parts of animals, that imbibes and retains *fire* for many years.

But in all these ways it does not appear that any *fire* is excited or generated of what was not *fire* before; for if in a severe winter's day you rub a plate of gold briskly against another, they will both grow hotter and hotter by degrees, till at length they become red-hot, and at the point of melting; and yet all this time the plates lose nothing of their weight, but swell and grow bigger in all their dimensions.

Hence it follows, that the particles of the gold are not converted by the friction into *fire*, but that the *fire* excited before; and all the effect of the friction, &c. is to collect or bring together a quantity thereof before diffused throughout the atmosphere.

In effect, there is no making or producing of *fire de novo*; all we can do is, of ignitable, to render it sensible; i. e. to collect it out of a greater space into a lesser, and to direct and determine it to certain places. This is effected as above mentioned by motion, attrition, &c.

The sun also contributes very much to the bringing of *fire* to light, by means of his rapid motion round his axis, whereby the fiery particles every-where diffused are directed and determined in parallel lines towards certain places, where their effect becomes apparent.

Whence it is that we perceive the *fire* or heat when the sun is above the horizon; but when he disappears, his impression or pressure being taken away, the *fire* continues dispersed at large through the ethereal space.

In effect, there is not less *fire* in our hemisphere in the night-time than by day, only it wants the proper determination to make it perceived.

Another way of rendering it sensible, is, by collecting the parallel rays into a less compass, by means of convex glasses, or concave specula. See *BECKSTEIN-GLAS*.

From these various ways of kindling *fire*, or producing heat in bodies, Dr. Franklin conjectures, that the *fire* exhaled in these bodies, though in a quiescent state, before it was by any of these means excited, disengaged, and brought forth to action and to view; and that it constitutes part, and even a principal part of the solid substance of bodies; so that kindling *fire* in a body is nothing more than developing the inflammable principle, and setting it at liberty to act in separating the parts of that body, which then exhibits the appearances of scorching, melting, burning, &c. He also supposes that particles of *fire* joined to those of air and water assist in raising vapours. See *EVAPORATION*, p. 412, &c.

To the same purpose, Boerhaave maintains, that this elementary *fire* is present every-where, in all bodies, in all space, and at all times, and in equal quantities; for go where you will, to the top of the highest mountain, or descend into the lowest cavern, whether the sun shine or not, in the coldest winters, or the most scorching summers, by one or other, or all of the means above mentioned, may *fire* be collected. In a word, there is no assignable physical point without *fire*; no place in nature where the attrition of two ticks will not render it sensible. So long as *fire* remains equal and undetermined in any place, it does not discover itself by any effect. In the severest weather we perceive no influence or effect of *fires*; when, at the same time, being collected and determined by attrition, it becomes manifest.

My changing *fire* out of its indeterminate state, and impelling it in converging lines, its momentum is increased; whence the phenomena of burning-glasses.

But how attrition, crude vegetables, &c. contribute towards altering the direction, &c. of *fire*, does not easily appear.

2. But in what manner *fire* is collected in bodies, upon a cessation of the collecting cause, is soon disappears again, unless it be supplied with a pabulum or fuel; and in this case it becomes *consumptive*.

By pabulum or fuel of *fire*, we mean whatever receives and retains *fire*, and is consumed, or at least rendered ignifiable thereby.

The only pabulum of *fire* in all nature is the oil of sulphur, or fat, or rather the phlogiston of bodies; and bodies are only fuel, on account of the oil or phlogiston they contain. For oil and sulphur were names which the ancient chemists indiscriminately gave to substances into the composition of which a great quantity of PHLOGISTON enters.

Hence, 1. All vegetables, not too moist, nor too dry, afford such a pabulum, particularly those which contain the greatest quantity of oil, as balsamic and resinous woods, &c. 2. All vegetable and animal coals are a proper pabulum for maintaining of *fire*, as being only the parts of vegetables and animals which have exhaled their water and salt, and retained the oil alone inhering in a black form in their earth. 3. All fossil and bituminous earths, turfs, &c. 4. All mineral sulphur, whether pure, or joined with earth, stone, or metals, as pit-coal, &c. 5. The fat and dung of animals. And 6. Several productions of chemistry, as oils, inflammable spirits, &c. afford also a pabulum for *fire*. See *COMBUSTION*.

This *fire* which burns combustible bodies requires air to sustain it; which taken away, the *fire* is immediately dissipated, as appears from the experiments in ovens; except in the case of substances into the composition of which nitre enters; for these will burn in vacuum, in fixed air, and under water, as is evident in some rockets which are made for this purpose.

VOL. II. N° 120.

And yet *fire* does not immediately bear or endure the air, but always repels it, and by that means forms a kind of vault or aerial furnace all round, which, by its weight and the pressure of the incumbent air, acts on all the particles or corpustcles that would make their way through it, and thus retains the *fire*, and applies it to the combustible matter.

Hence, the heavier the air, the more vehement the *fire*; and accordingly, in still cold weather we observe the *fire* to act with more violence than in warm weather.

But whether the air retains *fire* by its weight alone (which water itself would do) may be questioned; and whether its elasticity does not contribute something thereto; as also, whether there be not some farther unknown property in the air that has a share in this effect may be doubted. Something of this kind one would suppose from hence, that all air is not proper to maintain flame. Probably air is capable of receiving only a certain quantity of the phlogiston or inflammable principle from bodies in a state of combustion; and when it is saturated, it can no longer serve the purpose of maintaining flame. See *AIR*, *PHLOGISTON*, and *PHLOGISTON*.

This *fire*, in a burning combustible matter, affords a shining *fire* or flame, or both, according to the diversity of fuel, and frequently also smoke, soot, and ashes. Shining or luminous *fires* seem to be elementary *fires*, attracted towards the part of sulphur or oil with such force and velocity, as to move and shake them very violently, whirl them about, divide, and atomize them, and thus render them volatile, and ready to be expelled; while in the mean time the air, making its vault all round, retains and keeps them in, attracts them to the sulphur, and keeps them still collected in their place or pabulum, while the combustible matter is diffused all round. Flame seems to be nothing but a thick sulphur, agitated, as before, by elementary *fires*; so that the *fire* is driven with a great motion around the revolving particles of the sulphur. See *FLAME*.

Soot seems to be produced, when *fire* and sulphur cannot break into a flame, being a sort of coal consisting of a thick sulphur, and an attenuated oil with earth and salt. See *SOOT*.

Smoke seems to be the combustible matter when it begins to be rekindled by the elementary *fire*; for it this smoke be afterwards passed through a flame, it will itself become flame as before. See *SMOKE*.

Lastly, ashes are the earth and salt which the *fire* leaves unmoathed. See *ASHES*.

Fire may be distinguished into *flaming* and *not flaming*; for the there is *fire* which does not give light, is evident hence, that a piece of iron taken out of the *fire* before it be red-hot shall yet give *fire* to sulphur.

Shining *fire*, again, may be subdivided into two kinds: that which warms, excites but does not burn; and that which does not warm, as that collected in poured filices, rotten wood, &c. the oil whereof, beginning to be agitated and atomized, produces light without any heat, so far as the thermometer may be a rule of judging.

Among the number of these lambent or innocent flames, is the shining of meat at certain times. It has been usually supposed that this was owing only to the porrefaction of the meat, and that it never shone till thinking, or nearly so, but experience proves the contrary. We have in the Philosophical Transactions an account of a piece of veal which was adhered to flame the night after it was killed, and yet when eaten the day afterwards was perfectly sweet; and a part of it that was kept by way of experiment continued good many days after. This is not of the nature of common *fire* or flame, and not only differs in not burning, but in this also, that it is not extinguishable in water. A person thinking this piece of veal had the flame covering his whole hand, and that continuing even when he had put it under water; but the wiping it with a towel carried it all off and destroyed it. It is not uncommon to find the guts of hogs, when dressed for the making what they call chitterlings, and put into the pickle, shine in this manner. Some of the pieces while under this management usually swim on the water, and others sink in it. Those which swim are the only ones that shine. The light upon them is as bright as the strongest moonshine, and may be communicated to a person's hand by rubbing the pieces on it, where it will continue to be bright a long time without any sensible heat. The face and hands of a person being rubbed over with one of these shining pieces of the chitterling, not only appear bright and flaming, but are made to look considerably larger than they really are; and a person who had a mind to raise flowers of ghosts and apparitions might easily do it by covering the whole body of a man with this flame, and making him appear a *fiery* giant to all that saw him.

Mackerel in pickle will usually become luminous in some degree a little before they stink, but it is rarely that the

6 H

light

light is great; and when it has once happened, it is not easy to hit the same again, on a second trial, though all the ingredients of the phlogiston are kept the same in the phlogistons. Worms are often found luminous on their fore-sides, and this is the same worms are not always so, and what Pliny reports of the *Strophodon*, and that it was found to be true, perhaps may not always hold, in a future experiment. Philosoph. Trans. N.º 174. See DIAPHANITY.

One of the most regular kinds of luminous fire is that discovered at certain times on the sea-water, and on other water in which there are fish or other sea productions kept. We have in the Philosophical Transactions an account of some water in which mackerel were boiled, and afterwards kept, which became blackish and thick after two or three days, and then would sparkle on the touch of a finger. The fish also were luminous, especially about the gills, and the water, when stirred about with the hand, would appear to brighten the whole surface, that the appearance was like that of water in motion, as which the moon shines very strongly.

In the moon summer the fire occurs in many places, will sparkle and shimmer the breaking of its surface. Where a ship makes a good way in the night, in many seas, the whole breaking of the water will appear behind it as if on fire, sparkling and dancing all the way that it moves from the difference in the weight of the ship. Philosoph. Trans. N.º 174.

There does not always need the motion of a foreign body in the sea to occasion this sort of phlogistons, but the waves beating against one another will often occasion it in great plenty; and sometimes the waves washing against the rocks or against the shore, will yield a long course of light the whole night. This is no where to be remarkable as at the breaking the waves there are often all on a sudden to appearance, from the effluence of this luminous matter, as the waves will break upon the shore.

This flaming and sparkling of the surface of the sea is wholly owing to the peculiar quality of the water; and in general, the thicker and fouler the sea is, the more light it shows on being stirred in the night. A cloth dipped in the sea-water will sometimes be thick as if dipped in a solution of glue; in this case it will afford much brighter and more luminous sparks in the drying; and this sea-water will give much more fire from the motion of the ship than any other. In many places the surface of the sea is found covered with fiery matter of a reddish or yellowish colour, looking like saw-dust, and seeming to be the ordure or excrement of some sea-animal. This matter is always of a viscous nature, and the sea-water is viscous and glutinous wherever this is found, and gives more light on the moving than any other water. In the Northern seas there are sometimes seen whole banks, as it were, of this matter, the surface of the sea appearing wholly covered with it for several leagues; and this is often luminous all over in the night though not stirred by any ship, or even by the motion of any fish. Many of the sea fish have a viscous matter about their gills, especially when they have been some time dead. These, when kept in sea-water, have so much of this luminous property, that all that part appears as soon as taken up of the brightness of a flaming coal, and gives a light which is easy to read by. A piece of thick rubber on the gills of these fish will become luminous wherever it has touched them, and will continue so as long as it retains any of the moisture, but as that dries the light will fade and go off; and it may be revived again on touching the fish a second time. Observe, for *Philos.* p. 289. Jones's *Abstr. Philog.* Trans. vol. v. part ii. p. 213. See a more particular account and explication of this phenomenon under the article *Luminousness of the Sea*.

Of *phlogiston*, and at the same time *burning fire*, the principal sort of the fire, as it is called; though, whether the fire be really emitted from the body of the fire, or whether it be only the common vague universal fire determined by the fire, is not easy to say; this fire we more usually consider under the denomination of light. This *phlogiston*, in calcining certain bodies, makes some addition to the weight thereof.

Thus, antimony exposed in the focus of a burning-glass will smoke a considerable time, and the greatest part of it will seem to evaporate in fumes; but, if afterwards tried by the balance, it will be found to have gained in weight; and if it be again exposed in the focus of a larger glass, it will again emit fumes, and yet still be increased in weight.

Du-Clos found, that a pound of regulus of antimony, finely powdered, and exposed to the focus of a burning-glass, required in the space of an hour an increase of weight equal to a tenth part of the former weight: the same fact was also observed by Homburg with regard to antimony, and by Du-Hamel in several other minerals.

Zambachius found that lead liquified in the focus of a large speculum, and afterwards calcined and converted into glass, gained an increase of weight, though part of it evaporated in smoke. Nor is this increase of weight peculiar to substances calcined by solar fire. It is well known that 100 lb. of lead calcined in a fierce fire yields 110 lb. of mineral. Hellos, by reducing 4 lb. of zinc into a calx, obtained 3 lb. 14 ounces of very white and fine calx, 2 ounces and 2 drams of coarser and whitish calx, and an ounce of earth, though in the mean while part of the metal had escaped in smoke. Geoffroy found that bismuth acquires in calcination an increase of 1/4th of its original weight. The calx of tin is also known to gain 1/4th in weight. An ounce of filings of copper exposed to a wheel-fire for the space of three hours, and afterwards left to cool, had acquired an increase of 49 grains. Loni, according to the experiments of Mr. Scheffer, published in the *Physico-Mathematica* for the year 1757, receives by complete calcination an augmentation of one third of its weight; and it has been lately observed by Professor Bingham, in his *Observationes Academicæ de Affinitatibus Magneticis*, published at Leyden in 1778, that a quantity of the filings of iron which weighed one ounce or 480 grains before, was exposed to the fire, after eleven calcinations, increased in weight 149 grains; in the first calcination, which was the weakest, and in which all the filings were not red-hot in the crucible, the weight of the ounce increased 2 grains; in the second, in which the phlogiston was inflamed, and the whole mass had a white heat, the weight of the ounce was increased during the space of half an hour 34 grains; in the third, during a like interval, 50 grains; in the fourth, 18 1/2 in the fifth, 15 1/2 in the sixth, 7 1/2 in the seventh, 6 1/2 in the eighth, 9 1/2 in the ninth, in a new crucible, 5 1/2 in the tenth and eleventh, in the same crucible, one each. From other experiments this learned professor concludes, that the condition which is necessary in order to the augmentation of the weight of iron by fire, is, that the phlogiston be previously consumed; and he is of opinion, that the same rule holds with respect to the augmentation of weight in other metals. M. de Buffon, in the first volume of his *Supplement to his Natural History*, 1734, recites some experiments which he had made on coherent masses of iron, and from which he inferred the ponderosity of fire. In one of his trials he found a ball of iron which weighed 49 lb. 9 ounces when cold, 10 weight when heated to a white heat 49 lb. 11 ounces, which gives an augmentation of 10 1/2 grains to the pound. These conclusions of Buffon have been since invalidated by some experiments of Dr. Roebuck and Mr. Whitehurst; the former used two accurate balances; one of which, with the weight of a pound, would turn with one-tenth of a grain; and the other with a weight of half an ounce in each scale, would turn with the one hundredth part of a grain. A piece of iron of nearly one pound weight having received a white heat, was found to have lost scarce a grain when it was cold; and another piece of about five penny-weights weighed somewhat more when it was cold than when it was hot. By other experiments since made in the presence of several members of the Royal Society, it appeared that cylinder of iron brought to a white heat, and then weighing 55 pounds, on being suffered to cool, seemed gradually to acquire weight; and about twenty-two hours after it had begun to cool, was found to have increased in weight 6 penny-weights, 17 grains. The beam used on this occasion was so nicely constructed, that, when it was loaded with the great weight above mentioned, the scale evidently turned with 4 grains.

The experiments of Mr. Whitehurst were made with small masses; but with a balance so nice as to be sensibly affected by the two thousandth part of a grain. A penny-weight of gold made red-hot, and brought gently to a state of fusion, became apparently lighter; but on cooling, its former weight was perfectly restored. The same quantity of iron likewise seemingly lost weight on being equally heated; but its weight was visibly augmented on becoming cold. Mr. Whitehurst accounts for the apparent fallacy in M. de Buffon's experiments, by supposing that the heat of the large mass of iron employed by him had a greater effect on the arm of the beam from which it was suspended than on the other; and that by expanding or lengthening the former in a greater degree than the latter, it produced the preponderancy on that side which M. de Buffon ascribed to the particles of fire contained in the metal. Philosoph. Trans. vol. lxxi. part. ii. art. 31. p. 509. art. 38. p. 575.

M. Marggraf, in his experiments on *PLATINA*, found, that after exposing 2 ounces of crude platina in a suffocating dish under a muffle to a strong fire for two hours, and suffering it to become cold, it weighed 2 ounces and 10 grains, or one part in ninety-six more than it did at first;

first; and an ounce of platina in a covered crucible, placed in a melting furnace, and exposed between three and four hours in the strongest fire of all the furnaces in his laboratory, weighed but 6 grains, or about one part in eighty more than at first. *Acta Chemica*, tom. iii. p. 113.

Mr. Macquer put an ounce of platina into a German crucible, and exposed it to a strong fire for fifty hours; and on weighing the platina after the operation, it was found to be increased 14 grains, or allowing 576 grains to the French ounce, about one part in forty-one.

The same platina submitted to another similar operation, received a farther increase of 4 grains; the augmentation in all being 18 grains, or one part in 30. This increase of weight he supposes to be owing to the calcination of some heterogeneous substances mixed with the platina.

Dr. Lewis, having picked out from platina 360 grains of the larger and brighter particles, and the same quantity of the blackish dust separated from it by a sieve, put the two parcels in two smooth scorifying dishes, and kept them under a muffle in very strong heat for five hours, and when cold the picked platina weighed with great exactness was found to have gained 4 grains, or one part in 180, while the dust was increased near 9 grains, or one part in 40. *Comm. Philol. Techni.* p. 462.

The conclusion which some philosophers have drawn from these experiments, and others of a similar nature, is, that fire, by adhering to certain substances increases their weight, and is therefore ponderous like other bodies; an opinion which seems to have been suggested even by the ancients. See Lucretius, lib. ii. v. 185. But however the question concerning the nature and gravity of fire may be determined, the increase of weight acquired by calcined substances is most satisfactorily accounted for by the modern discoveries with regard to fixed air. See CALCINATION and *Potential Heat*.

See on the subject of this article Boerhaave's *Chemistry*, vol. i. part 2. of *Fire*, and Muehlenbroeck's *Introduct.* ad *Phil. Nat.* tom. ii. cap. xviii. p. 609. &c. &c. *proli.*

Beside the solar, there is likewise a subterranean fire.

This appears in digging under-ground; for the first globe next to the surface is warmed by the heat of the sun, and as you go deeper you will find it colder; whence, even in hot countries, they have conservatories of ice at some depth under ground, till, arriving at a certain depth, viz. forty or fifty feet, it begins to grow warmer, so that no ice can there subsist, and at a yet greater depth, it is so hot as to take away respiration, extinguish candles, &c. and if the miner will venture farther, and carry a candle along with him, he frequently sets the whole place in a flame, the sulphurous fumes, rendered volatile by the subterranean fire, catching flame from the candle.

Whence it is alleged by some that there is another source of fire, or, as it were, another sun in the bosom of the earth which gives motion and life to every thing growing in or upon the globe, and even that the centre of the earth is mere fire, which fire is likewise argued to be perpetual, from volcanos or burning-mountains, which have been known to cast up fire from the earliest account of time. See *HEAT* and *VOLCANO*.

There are two great fires, therefore, the higher or solar, and the lower or subterranean.

The effects of this last seem wholly the same with those of the common culinary fire; for burnt coals, cinders, and melted minerals are thrown out by the burning mountains; and hot springs, steams, vapours, &c. are found in several parts of the globe, rising nearly in the same manner as if they were produced by the heat of a common furnace. Whence there is little room to doubt but that the subterranean fire is not like the celestial or solar but the culinary.

Martin in his *Atlas*, tells us, that there are pits of natural fire in China which are capable of broiling meat, but will not consume wood; but we have no authentic testimony of any eye-witness to this strange fact.

FIAT, in *Chemistry*, is the great instrument by which most of the operations of that art are performed.

The kind, degree, direction, &c. of fire are things the chemist is principally to attend to. The diversity of fire makes a great difference in the result of the experiments; so that the same effect, e. g. shall not arise, if an experiment be made with the fire of spirit of wine and that of pit-coal.

And to this cause Mr. Boyle, in his *Treatise of the unexpected Failure of Experiments*, attributes it, that a great many experiments successfully tried by some have not succeeded with others.

The fire chiefly required by the chemists are such as yield no fumes or remains, no salt nor smoke; and such alone are those of the sun and spirit of wine. Those which come next in purity are oils distilled *per se*, which lose their earth and salt by their boiling and agitation in

the water, so that the oftener the distillation is repeated, the purer they are rendered. After these the best is sulphur.

Indeed, the very manner wherein the fire is blown is found to have some effects. Thus, Acquila, lib. iv. cap. 52. relates, that in Peru, when they would melt and separate their silver from the earth, &c. the fire be blown up with bellows, the fusion will not succeed; nor will any other fire do, but that blown by the wind which rises from the fall of some water; so that they are forced to have recourse to large wheels laid to the feet of large mountains, where there are cascades to convey the wind generated by this fall of water to their works.

The degree of fire, or the collection and direction of fire to the degree proper for each operation, constitutes almost the whole art of chemistry.

Now the greater or less force of fire depends altogether on a greater or less quantity thereof collected into a focus; for as to its motion it does not seem to be in our power to alter it, or to make any increase or diminution of the force of the fire on that account.

The chemists in all ages have been accustomed to speak of the degrees of fire, which they usually divide into four; but very little accuracy was found on this head till the method was discovered of applying the thermometer of Fahrenheit to the measurement of the progress of heat by certain and invariable rules. On this basis Boerhaave has established the chemical doctrine of the power of fire, and divided it into six degrees; and these are the degrees of fire, which our chemists allude to, when they now mention the force of fire in their operations.

The first degree is that by which nature performs the office of vegetation in plants, and by which chemistry initiates and does the like. This commences from the highest degree of cold, which in Fahrenheit's thermometer is marked at 1°, and ends at 80°, since in this whole interval vegetables of one kind or other give indications of life and growth; so that if all the plants with which we are at present acquainted be examined, by this degree of heat, contained within their limits, we shall find some plants or herbs that continue in activity in almost every one of these intermediate degrees.

Hence it appears, that the first degree of fire, by duly conducting this degree of heat in an artificial flow, might contrive to cherish and forward the vegetation of various plants; and in the offices of chemistry a furnace might be made for raising any degree of heat within these limits, on which a vessel of water might be set, and a thermometer applied to it, the rise or fall of which indicates the degree of heat required. Glass vessels placed in this water thus tempered might be used for containing those substances which are to undergo this degree of fire. Thus, the fragrant scent of roses may be communicated to oil, by putting the insoucious and insipid oil of olives in a tall clean chemical glass, and digesting it in a heat of 50 degrees with the most fragrant roses gathered just as they are opening in the morning; the application of a similar degree of heat would impregnate alcohol with the purest spirit of saffron.

The second degree of fire may be commodiously measured by the heat that is at some time or other observed in healthy bodies, and may be supposed to commence at the 40th degree of the thermometer, and to end about the 94th. Animals may submit if their humours have any degree of heat in them between these limits. The eggs of insects submit unhurt during hard winters, and hatch in the succeeding spring. Fishes, both of the sea and of rivers, live in water which is only 34 degrees warm; and fishes that have lungs, and all respiring animals in a state of health communicate to their humours a warmth of 92 degrees; and therefore, the limits of this degree are fixed at 92 and 94. Within the compass of this heat are included the vital actions of animals, the fermentation of vegetables, and the putrefaction both of vegetables and animals; and likewise the generation, breeding, hatching, birth, and nutrition of animals. Some determine the standard of this heat by applying a thermometer to a hen brooding on her eggs, and by keeping a fire continually to this degree, chickens have been hatched. This degree of heat is employed by chemists to prepare their elixirs, volatile alkaline salts, and their tinctures. However, it appears from later observations that the limits of animal heat are considerably greater than those which the celebrated professor has above stated.

The third degree of heat extends from the 94th degree of the thermometer to the 212th, at which water generally begins to boil. Through this space the water and native spirits are separated from all vegetables and animals, and the residuum becomes dry and durable. The essential oils of plants become volatile; the salts and oils in the fresh juices of animals are scarcely raised, but the

juices

juices dry into a thick, hard, brittle, insipid, inodorous substance, which will keep for years without any considerable alteration. This degree of heat is for the distillation of oils and medicinal waters of vegetables. The fanguiferous ferrous juices of animals coagulate in boiling water into malle that may be cut slender; all their solids are converted into a thick tenacious liquid, and it is consequently destructive to all animals. See *ANIMAL HEAT*. The fourth degree of heat may be reckoned from the degree 212 to 600, within which limits all oils, saline liquors, mercury, and all of vitrol are distilled; lead and tin will also melt and mix together. The oils, sals, and gummy juices of animals and vegetables are rendered volatile and aerid, and become more or less calcareous: their solid parts are calcined, and lose their distinguishing qualities and proper virtues; and with this degree of *fire* salphur and sal ammoniac are sublimed.

The fifth degree of *fire* is that which fuses the other metals, beginning at the degree 600, and terminating at the degree of heat capable of melting iron. Glass, gold, silver, copper, and iron remain long unchanged; all other hard bodies become white with this heat, the fixed salts of vegetables and sulfurs melt, lose most of their oils, acquire an increasing alkaline serenity, and with sand or lime are converted into glass. Limestones are calcined, and all other bodies either vitrify or become volatile, and are dissipated into the air.

The sixth and highest degree of *fire* is that produced either by a lens or a burning speculum, which hardly any substance is able to resist, and even the gold and diamond, and plasma are considerably altered by it.

The usual effect of *fire* is the vitrification of fixed bodies, and this, says Boerhaave, the ancient magi of the East found to have been appointed of, as they predict the destruction of the world by *fire*, and its mutation into transparent glass. Boerhaave by Dallow, ubi supra, p. 261, &c.

This last degree was first discovered in the year 1690 by Mr. Tschirnhausen, whose burning glass rendered every thing, even gold itself volatile.

Beside these six degrees, the chemists have several intermediate ones; all which, however, may be easily reduced to the former.

As the *boiling fire*, or *water equi*, which is the heat of a dunghill.

The *tabernacle fire*, *arroyon*, &c. explained under the article *BALNEUM*.

The *neted or immediate fire*, which is the common *fire* applied under a vessel.

The *fire* of a lamp, which is moderate and equal, and may be increased by the addition of more wick, used by chemists, &c.

The *used fire*, which is lighted all round a crucible or other vessel to heat it all alike.

That called by *pyrophorus*, which is when the vessel is not only encompassed round, but covered over with *fire*.

The *reverberatory fire*, when it is in a furnace close to a top by which the *fire* is reflected back, and all round upon the vessel.

The *melting or fusing fire*, for the solution and calcination of metals and minerals.

The *glass-house fire*, for the vitrifying of the ashes of vegetables.

And the *Olympic fire*, which is that of the sun collected in the focus of a burning mirror.

Hot fire is a term denoting the greatest degree of heat employed by the manufacture of sal ammoniac in Egypt.

To the several degrees of *fire* required, several forms of furnaces are accommodated, which see under the article *FURNACE*.

There are five principal ways of altering the degree of *fire*.

For *fire* differs 1. According to the weight of the pabulum or fuel, it being a rule, that the heavier the fuel or combustible matter is, the more vehement, *ceteris paribus*, is the *fire*. Thus, spirit of wine affords a weaker and less destructive *fire* than oil; and this than pitch, and so on; the heavier and grosser, still the fiercer.

2. According to the quantity of the pabulum or fuel.

3. According to the distance of the *fire* from the object; it being a rule, that the heat of the *fire* at different distances is reciprocally as the squares of those distances.

4. By the introducing or blowing of air into the *fire*, it being a rule that the stronger the current of air or wind is, provided it be not so strong as to break the vessel for mix or scalt. I comment on the *fire*, the more is the *fire* increased. For a brisk blowing puts the minute parts of the pabulum into a greater motion; whence the greater attrition arises, and of consequence more *fire* is collected.

5. According to the solidity or resistance of the medium between the *fire* and the object; for the more solid the medium, the greater quantity of heat, *ceteris paribus*, does it receive from the *fire* and communicate to the object.

Thus, a vapour-bath communicates much less heat to the bodies distilled by it than a water-bath, and this again less than a bath of steel-slings; for all bodies exposed to the *fire* grow hot in proportion to their specific gravity. Thus, if a piece of metal be put in water, and both far over the *fire*, while the water only grows lukewarm the metal shall be so hot as to be pain touching; and thus, a key in a person's pocket sitting near the *fire* shall frequently be very hot, while his cloaths themselves have not any sensible warmth. Indeed, this rule admits of some exceptions; for we have oils lighter than water, which yet admit of triple its degree of heat before they boil.

It is a great controversy in chemistry, whether *fire* when applied to bodies daily separates and dissolves them, or whether it does not also really and absolutely change them.

Mr. Boyle, in his Sceptical Chemist, we think, has abundantly proved, that *fire* really alters bodies, and that the parts or elements procured from bodies by *fire* did not exist as such in the bodies themselves.

Add, that *fire* does not only separate and decompose, but it also compounds and mixes different bodies to intimately together, that the new formed substance appears perfectly simple, and is not liable to any alteration from its power afterwards. Boerhaave.

Fire, in *Medicine and Surgery*, is used in the same sense with cautery. See *CAUTERY* and *CAUSTIC*.

Fire also gives the denomination to divers diseases, as

Fire, St. Anthony's, by physicians more usually called *erysipilas*. See *ERYSIPELAS* and *ANTHONY*.

Fire, walking, called also *Will-wish-a-wisp*, *Jack-in-a-lantern*, *ignifatus*, &c. See *IGNIFATUS*.

Fire, in *Theology*, is frequently understood of the punishment of the wicked after death. See *HELL*.

It is supposed the world will perish at last by *fire*. See *CONFLAGRATION*.

God has made several revelations of himself under the appearance of *fire*; he appeared to Moses under the form of a *fire* burning in a bush; the Holy Ghost descended on the apostles in tongues of *fire*; and the camp of the Israelites was guided and conducted in the night time by a pillar of *fire*.

The Persians adored God under the image or representation of *fire*, because it is *fire* that gives motion to every thing in nature. They are said to have in that empire five full subsisting, which have burnt many thousand years. See *FIRE*, *revolving*, *GABRES*, and *MAOI*.

The Hebrews kept up the *holi fire* in the temple. This *holi fire* descended from heaven, first upon the altar in the tabernacle at the consecration of Aaron and his sons to the priesthood, Lev. ix. 24, and after wards it descended anew on the altar in the temple of Solomon, at the consecration of that temple, 2 Chron. vii. 1. And there it was constantly maintained by the priests day and night, without suffering it ever to go out; and with this all the sacrifices were offered that required *fire*. This *fire*, according to some of the Jewish writers, was extinguished in the days of Manasseh; but the more general opinion among them, is that it continued till the destruction of the temple by the Chaldeans; after that it was never more restored; but instead of it they had only common *fire* in the second temple.

The *Vestal* were appointed expressly to keep up the sacred *fire* of the Romans.

Vulcan was worshipped among the ancients, and particularly the Egyptians, as the inventor of *fire*; and Boerhaave has made it highly probable, that the Vulcan of the heathens was the Fabul-Cain of the Hebrews, the first who appears to have known the use of *fire*, and to have applied it in the fusion of metals, and other preparations of chemistry.

Fire, in the *Magic*. To give the *fire* to a horse is to apply the firing-iron red-hot to some preternatural swelling in order to disperse it, which is sometimes done by clapping the firing-iron upon the skin without piercing through. We give the *fire* to *PARRY* knots, by running a pointed burning-iron into the ulcers. We likewise give the *fire* for wincles of the patients. See *FIRING-IRON*.

Fire, in the *Military Language*, is sometimes applied to the *fire* lighted in an army in the night-time.

But the term *fire* or *fray* is more frequently used for the discharge of the *fire*-arms, or the first made on the enemy from the artillery, &c. And accordingly it is used as a word of command to soldiers of all denominations to discharge their *fire*-arms, grenades, cannon, &c. The

fire of the infantry is by a regular discharge of their firelocks, by platoons, divisions, &c. that of the cavalry with their lances and pistols, and that of the place belated from their artillery. See EXERCISE and FLAME.

In fortification, the *fire of the place* denotes the flank, or that part of the curtain where the line or defence terminates, from whence they *fire* to defend the opposite face of the bastion.

Fire-iron is a small iron dart furnished with springs and bars, together with a match impregnated with powder and sulphur, which is wound about its shaft. It is used by privates and pikemen to fire the falls of the enemy, and for this purpose is discharged from a musket or a swivel-gun. The match being kindled by the explosion, communicates the flame to the fall, against which it is directed where the arrow is followed by means of its bars and springs. As this is peculiar to hot climates, particularly the West Indies, the falls being extremely dry are infinitely for *fire*, and the *fire* is conveyed to the match, triggering, and finally to the vessel itself.

Fire-works. See ARMS.

Fire-balls a composition of meat powder, sulphur, saltpetre, resin, pitch, &c. about the bulk of a hand-granade, made of an iron shell, filled and covered over with several coats of the above mixture, the last coat being of grained powder. This brown paper made into the form of a shell adapted to the size of the mortar, and filled with an equal quantity of sulphur, pitch, resin, and meat powder well mixed and put in warm, will answer the purpose as well as any thing else. This is to be thrown into the enemies works in the night-time, to discover where they are, or to fire houses, galleries, or blinds of the besiegers. The balls used for this intention are prepared with melted powder, saltpetre, sulphur, resin, pitch, or iron filings, fire-raw saw-dust boiled in saltpetre ley, and larch wood charcoal, well rammed into a shell, having various holes filled with small barrels loaded with musket-balls, and impregnated in melted pitch, resin, and turpentine oil. They are sometimes armed with spikes or hooks of iron, that they may not roll off, but stick or hang where they are desired to have any effect. See BALLS.

Fire-bars, in our Old Writers, is used for a beacon. *Quæ sunt distantia inter vigiliarios foci, sunt & fire-bars, quæ minus distant in quietis horis, et magis in potestate per vigiliarios, quædamque vigiliarios, præsumunt.* Ordin. Observant. Temp. Edw. II.

Fire-barrel See BARRELS. Those used in FIRE ought to be of a cylindrical form, as most suitable to contain the matter with which they are filled, and more convenient for moving them between the wheels in the fire-room. Their inside diameters should be less than 21 inches, and 30 inches are sufficient for their length. The bottom parts are full well forced with their double-dipped reeds placed upright, and the remaining vacancy is filled with *fire-barrel* composition, being a mix of corned powder, pitch, and saltpetre, well mixed and melted, and poured over them. The proportion and quantity of ingredients for one barrel are 130 lb. corned powder, 60 lb. of pitch, and 10 lb. of saltpetre; and the priming composition for one barrel is 100 lb. of corn powder, 50 lb. of saltpetre, 40 lb. of sulphur, 5 lb. of resin, and three pints of oil. There are five holes at three-fourths of an inch in diameter, and 2 inches deep, formed in the top of the composition while it is warm, one being in the centre, and the other four at equal distances round the sides of the barrel. When the composition is cold and hard, the barrel is primed by filling these holes with *fire-composition*, which is firmly driven into them, so as to leave a little vacancy at the top to admit a brand of quick-match twice doubled. The centre hole contains two brands at their whole length, and every brand must be driven home with melted powder. The loose ends of the quick-match being then laid within the barrel, the whole is covered with a dipped curtain, fastened on with a hoop that lies over the head of the barrel, in which it is nailed. These barrels should be made very strong, not only to support the weight of the composition before firing, when they are moved from place to place, but to keep them together whilst burning; for if the staves are too light and thin, so as to burn very soon, the remaining composition will tumble out and be dissipated, and the intention of the barrel, which is to carry the flame along, will be frustrated. Philosopher's Mar. Dick. and Miller, vol. v. p. 301.

Fire-shots, in Agriculture and Gardening. See GRASS, and Miller's Statist. vol. i. p. 36.

Fire, Gun. M. Mahudel has a dissertation on the origin of *gunpowder*, wherein he endeavours to make it appear that Vol. II. N° 130.

they were unknown to the ancients, and consequently must be a modern invention.

He does not deny that the ancients had rejectings on occasion of the conclusion of a peace or alliance, or the news of a victory's being obtained against their enemies, on the third-day, proclamation, or marriage of their prince; as also when they recovered from a dangerous sickness; but, according to him, the *fire* on all these occasions served only to burn the victims of the sacrifice, and as these sacrifices were mostly offered in the night-time, the illuminations were only intended to give light to perform the ceremonies. Hist. Acad. Inscriptions, tom. II. p. 430, 431.

Fire-law (act) for necessary things, which, by the common law, tenants may take out of the lands granted to them.

Fire-roads. Church-wardens in London, and within the bills of mortality, are to fix fences or proper distances in streets, and written marks near them, and to keep in every house this marked instrument or key for opening the plug, and a large engine and hand-engine for extinguishing *fire*, under the penalty of 10*s*. The turn-cock whole water shall come first into a main pipe at a fire hall have 10*s*. the bill engine that is brought shall entitle to 30*s*. the second to 20*s*. and the third to 10*s*. 6 Ann. cap. 11. 13 Geo. III. cap. 72. To prevent *fires*, it is required that workmen in the city of London, &c. build all front and rear walls of brick or stone; and that the front walls be 12 inches above the gutter, and coped with stone, tile, or brick; and party walls between houses and houses, those belonging to houses the expense of building which is more than 1200*s*. to be of the thickness of 1 foot 6 inches, or 21 bricks in the wall, and of 2 bricks, or 1 foot 5 inches from thence to the gutter; and from the gutter upwards, 14 bricks, or 12 inches, and to be carried up to the full height of 21 inches above the adjoining gutters; and it is also required, that no chimneys, except the girders, binding, and chimney-pieces, and the temples under the same, shall be laid into such party-walls; and that there shall be 6 inches of solid brick well left at or between the ends of all walls, wall-pieces, and bind timbers. See BUILDINGS, and Stat. 7 Anne, cap. 17. 11 Geo. I. cap. 28. 17 Geo. II. cap. 30. and 4 Geo. III. cap. 14. And on the breaking out of any *fire*, all the neighbours and neighbours shall repair to the place with their ladders, and be assisting in putting out the same, and causing people to work. &c. No person shall be held criminal any person in whole house or chamber a *fire* shall begin, 6 Anne, 10 Anne, cap. 14. But if such *fire* happens through negligence or any default, such persons shall forfeit 100*s*. to be distributed among the sufferers, or, in default of payment, shall be committed to prison with bail, and their kept to hard labour for sixteen months. See ARMS.

All the laws relating to the extinction, &c. of *fires*, are introduced into one statute, and statutes repealed by 12 Geo. III. cap. 73.

Fire-work, in Natural History. See DAMPS.

Fire-water. We have a great number of mountebanks who have procured the attention and wonder of the public, by cutting of *fire*, walking on *fire*, washing their hands in melted lead, and the like tricks.

The most celebrated of these was our countryman Richardson, much talked of abroad. He first, as related in the *Journal des Savans*, of the year 1699, confined in a pure spirit of sulphur, whereupon he rubbed his hands and the parts that were to touch the *fire*, which burning and cauterizing the epidermis, hardened and enabled the skin to resist the *fire*.

Indeed, this is no new thing; Amb. Pare asserts he had tried on his self, that after washing the hands in urine, and with unicorn's urine, one may safely walk in melted lead.

He adds also, that by washing the hands in the juice of onions he could bear a hot shower on them while it melted lead.

Fire, Artificial. See FLUENTIA.

Fire-engine is a machine for extinguishing accidental *fires* by means of a stream or jet of water. The common squaring *fire-engine* consists of a lifting pump placed in a circular or cylindrical vessel of water, and wrought by two levers that act always together. During the stroke, the quantity of water raised by the piston of the pump forces with force through a pipe forced to the pump-barrel, and made capable of any degree of elevation by means of a yielding leather pipe, or by a ball and socket turning every way, forced on the top of the pump. The vessel containing the water is covered with a drainer, which prevents the dirt and filth poured into it with the water from choking the pump-work. Between the strokes of this engine the stream is discontinued.

for want of an air-vessel. However, in some cases, engines of this construction have their use, because the stream, though interrupted, is much freer than when the engine is made to throw water in a continued stream. The best engine of this latter kind is that of Mr. Newtham, formerly an engine-maker in London. A perspective view of the whole engine ready for working is represented in *Tab. Hydrostaticæ, fig. 3*. This engine consists of a cylinder AB about three times as long as it is broad, made of thick oak or plank, the joints of which are lined with flax-wool, and easily moveable by means of a pole and cross bar C in the fore-part of the engine, which is so contrived as to slide back under the cover of the cylinder, and at four fold wheels, two of which are fast at D and E. The hind axle-tree, to which the wheel E and its opposite are fixed, is fastened across under the bottom of the cylinder, but the fore axle-tree, bearing the wheel D, &c. is put on a strong pin of bolt strongly fastened in a horizontal position in the middle of the front of the bottom of the cylinder, by which contrivance the two fore-wheels and their axle-trees have a circular motion round the bolt, so that the engine may stand in firm on rough or sloping ground as if it was level. Upon the ground next to the hind part of the engine may be seen a leather pipe F, one end of which may be screwed on and at upon occasion to a brass cock at the lower end of the cylinder: the other end is inserted in the water, furnished by a pond, &c. for pipe, &c. and the pipe becomes a sucking pipe for furnishing the pump of the engine by its working, without pouring water into the cylinder. In the hind part of the cylinder is fastened a wooden trough G, with a copper grate for keeping out stones, sand, and dirt, through which the cylinder is supplied with water when the sucking pipe cannot be used. The fore part of the cylinder is also separated from the rest of its cavity by another copper grate, through which water may be poured into the cylinder. Those that work the pump of this engine move the handles visible at the long ends up and down, and are assisted by others who stand on two suspended wheels, throwing their weight alternately on each of them, and keeping themselves steady by taking hold of two round horizontal rails, H, I, framed into four vertical bands, which reach to the bottom of the cylinder, and are well secured to its sides. Over the hind trough there is an iron handle or key K, forming in open air a cock placed under it on the bottom of the cylinder, the use of which we shall explain in the sequel of this article. L is an inverted pyramidal box or case which protects the pump and air-vessel from damage, and also supports a wooden frame M, on which stands a man, who, by raising or depressing and turning about the front N, directs the stream of water as occasion requires. This front is made of two pieces of brass pipe, each of which has an elbow: the lower is screwed near the upper end, &c. (see *fig. 3*). The pipe that goes through the air-vessel, and the upper part screws on to the lower by a series of several threads, so truly turned as to be water-tight in every situation. The conic form of the spouting-pipe serves for withdrawing the water in its passage through it, which occasions a suction that produces such a velocity of the jet as to render it capable of breaking windows, &c. whilst the valves and leather pipes of the engine have sufficient water way to supply the jet in its greatest velocity. Leather pipes of considerable length may be screwed at one end to the neck of the engine, and furnished at the other end with a wooden or brass pipe for guiding the water into the inner apartments of houses, &c. Between the pyramidal box L and the fore-end of the engine, there is a strong iron bar O, lying in an horizontal position over the middle of the cylinder, and playing in bristles supported by two wooden stands, one of which, P, is placed between the two fore-wheels of the upper rails, and the other is hid in the inclosure over the hind part. Upon proper squares of this bar are fitted, one near each end, two strong cross-bars, which take hold of the long wooden cylindrical handles, by means of which the engine is worked; and the treadles by which they are adjusted are supported at each end by chains in the form of a watch chain, and receive their motion jointly with the handles that are on the same side, by means of two circular sectors of iron fastened together, and fixed upon proper squares of the middle horizontal bar; the two fore ones may be seen at Q; the two hind ones, represented on a large scale in *fig. 4*, differ from the former only in thickness: for the fore-ones are made to carry only one chain each, fastened by one end to their upper part, and by the lower end to the treadles; whereas the two of the two hind sectors are wide enough to carry two chains each: one fastened like those of the fore-ones for the motion of the treadles; and the other two chains are fastened by their lower ends to the lower part

of their sectors, and by their upper ends to the top of the piston bars, in order to give them motion. See *fig. 4*, in which the hind factors and their apparatus are represented, as they would appear to a person, standing between the two fore-wheels, and looking at the hind part of the engine. The square over the letter N is the section of the middle bar, on which, right over the two barrels, are placed the two factors HCA and DEA forged together. EGHK and *fig. 4* are the two piston rods; and the openings between the letters G, H, and I, are the faces through which the hind parts of the two treadles pass. L and M represent two strong rods riveted on the other side of the bars on which they are placed, and each of these is fastened to a chain like a watch chain, fixed by their upper ends to the upper extremities D and E of the iron sectors, by which they are drawn up and down alternately. These factors give also an alternate motion up and down to the piston-rods, by means of two other chains, left, while in the figure, in order to distinguish them from the others: these are fastened by their lower ends to the lower extremities of the sectors E and C, and their upper ends terminating in a male screw, are made tight to the piston rods at F and J, by two nuts. The shape of the piston-rods, and the size and direction of the chains that give them motion, are so contrived, that the vertical axis of the pistons is exactly in the middle of the breadth of the perpendicular part of the chains, and by the upper part of the piston rods taken together. PQ represents one of the two cross bars through the ends of which pass the long handles, to which the men apply their hands when they work the engine: these cross bars are fitted up the middle bar at some distance from the factors. The other parts of this useful engine may be understood by the help of *fig. 5*, which represents a vertical section taken through the middle line of the hind part of the engine, as also the section of an air-vessel, and that of one of the barrels, and likewise the profiles of the hind factors, and of several other parts. A is the section of the bottom of the cylinder, and C that of the hindmost axle-tree. DE is the vertical section of a strong piece of cast brass or hard metal, so worked as to have a hollow in it, represented by the white part, and fixed to the bottom of the cylinder: this reaches from the opening D through the cock W, and afterwards divides itself into two branches, so as to open under the two barrels; one of these branches is exhibited in the figure, and the other is exactly behind this. Through this channel, which may be called the sucking-piece, water is conveyed to the pumps by the pressure of the atmosphere, either from the cylinder itself, or from any place at a distance, by means of a leather pipe F, *fig. 1*, which screws on to the sucking-piece at D, *fig. 5*, under the hind trough Z, the grain of which is represented by the horizontal lines. FG represents the vertical section of another piece of cast brass or hard metal that may be called the communication-piece, having two hollows for conveying the water from under the two pistons to the two openings of the flanch of the air-vessel out of these hollows appears in the figure, the other lies exactly behind this, though not in a parallel direction. Between the section of the sucking-piece DE and that of the communication-piece FG may be observed the section of one of the plates of leather, which makes all tight, and forms one of the two sucking valves, of which there is another just behind this under the other barrel. RST is the section of the copper air-vessel, and TV that of the communication-piece; this vessel is screwed on to the hind part of the communication piece, and at top is fastened by a collar of iron to a cross piece of timber. Between the flanch of the air-vessel and the communication-piece may be observed the section of one of the plates of leather, making all tight, and screwing one of the two forcing valves, of which there is another just behind this, exactly over the other opening of the communication from the air-vessel. These valves are loaded with a lump of cast iron or lead, having a tail or ear let through the flap of the valve and compressed under it, and it is to be observed, that, though both the valves are represented open in the figure, they are never both open at the same time; for when the engine is not at work they are closed down by the weights on their upper surfaces; and when the engine works, two are shut, and the other two are open alternately by the motion of the pistons and the action of the atmosphere, together with the reaction of the air contained in the air-vessel. HI is the section of one of the barrels of the two pumps which are both sucking and forcing, as is evident from the position of the valves and the structure of the pistons, each of which is composed of two iron plates, of two wooden trowsers, and of two flat pieces of leather turning one up and the other down. LK represents one of the piston rods edge-wise, behind which is one of the chains,

chamber, the top screw of which, K, can only be seen. M is the end of the middle bar, and N a section of the hindmost of the two middle flanks which support the middle bar. O represents the end of the profile of one of the trussies, passing through the rectangular holes of the piston rods, as in fig. 1. The weight on these trussies brings them and the piston-rod down alternately, and they are raised up again by help of the other set of chains, one of which may be seen edge-wise in this figure, placed on the sole of one of the sectors, &c. See fig. 4. P, Q are part of the cross bars which carry the handles, seen edge-wise; and X, Y represents an iron handle, by the help of which the cock W may be placed in the several situations requisite for the use of the engine. The mechanism of the cock W may be understood by fig. 6, 7, and 8, which represent the horizontal section of it in three different situations. It has three holes that are left white in these figures. In fig. 6, the position of the cock is represented when the handle X or K is in a direction parallel to DZ, or to the middle bar, as in fig. 2, and fig. 3. In this position, the water supplied by the sucking-pipe enters at D, and proceeds directly through the cock W to the valve under the two pistons; and there is now no communication from the barrels with the cavity of the cylinder. In fig. 7, we have the position of the cock when the handle X, Y is turned one quarter of a revolution towards the eye from the last mentioned situation, in which case there is no communication from the barrels with the outer extremity of the sucking-piece, but the water poured into the fire and hind trough, and passing from thence into the cavity of the cylinder, enters the cock hole-wise at W, and turning at right angles through the cock towards E, proceeds to the barrels of the pumps. Fig. 8, represents the cock W when the handle is placed diametrically opposite to its last situation, in which case there is no communication from the under-side of the barrels with the cavity of the cylinder or the outward end of the sucking-piece; but this situation affords a communication from the cavity of the cylinder with the outside of the engine, and the water left in the cavity of the cylinder may by this means be employed when the engine has done working. These engines are made of five or six different sizes. See DeGouliers's *Courir de Exper. Philol.* vol. II, p. 308—318. The principles on which this engine acts, so as to produce a continued stream are obvious; the water, being driven into the air-vessel, as in the operation of common sucking and forcing pumps, will compress the air contained in it, and proportionately increase its spring, since the force of the air's spring will always be inversely as the space which it possesses; therefore, when the air-vessel is half filled with water, the spring of the included air, which is in original state compressed into the pressure of the atmosphere, being now compressed into half the space, will be equal to twice the pressure of the atmosphere; and by its action on the subjacent water will cause it to rise through the conduct pipe, and to play at jets of 32 or 33 feet high, shooting the effect of friction. When the air-vessel is two-thirds full of water, the space which the atmosphere really occupies of its full force; therefore, its spring being three times as great as that of the common air, will project the water with twice the force of the atmosphere, or to the height of 64 or 66 feet. In the same manner, when the air-vessel is three-fourths full of water, the air will be compressed into one-fourth of its original space, and cause the water to ascend in air with the force of three atmospheres, or to the height of 96 or 99 feet, &c. as in the following table:

Height of Height of the Projection of Height, so which the water compressed in the air's spring the water will rise

See Martin's *Philol.* Brit. vol. II, p. 69, &c.

FIRE-ENGINE is also a name frequently given to a machine for raising water by steam, more properly called **STEAM-ENGINE**.

FIRE, covering, in *Forma Trebley*, is a kind of reputed sacred fire worshipped by the GAVERS or GAVRAN in Persia. Dr. Mountain, formerly physician to the Czarina's army, has given the following account of it: this perpetual fire rises out of the ground in the peninsula of Abcheron, about twenty miles from Baku, and three miles from the Caspian shore. The ground is rocky,

over which is a shallow covering of earth. If a little of the surface be scraped off, and fire be applied to the hollow, it catches flame immediately, and burns without interruption, and almost without consumption; but it is ever extinguished unless some cold earth be thrown over it, by which it is easily put out. There is a spot of ground, about two English miles in extent, which has this property, where the earth continually burns, but the most considerable part of it is a hole about four feet deep, and fourteen in diameter. This fire is worshipped, and is said to have burned many thousand years. The cracks in the walls of the caravanserai, inhabited by the religious, are covered with flame, if a candle be held to them; and when there is occasion for a small light, no more is necessary than to stick one end of a piece of reed in the ground, and apply a lighted candle to the other; a flame will kindle at the top of the reed, and burn till it is extinguished by covering it. They burn flares into lime, by filling a hole in the ground with a heap of them, and bringing a lighted candle to the hole, upon which the fire kindles, and in about three days burns the flares sufficiently. The flame yielded by this fire has neither smoke nor smell. This fixed and eternal phenomenon is nothing more than an inflammable vapour, which issues in great quantity out of the ground in this place, and is supplied by the mud with which the adjacent country abounds. *Philol. Trans.* vol. XII, p. 174, p. 205.

1st, extinguishing of. The world has long been in an opinion, that a more ready way than that in general use might be found for extinguishing fires in buildings; and it has been generally attempted upon the doctrine of explosion. Zachary Grey was the first person who put this plan into execution with any tolerable degree of success. He contrived certain engines, easily manageable, which he proved before some persons of the first rank to be of sufficient efficacy, and offered to discover the secret by which they were contrived for a large premium given either from the crown, or raised by a subscription of private persons. But this scheme meeting with no better success than things of this nature usually do, he died without making this discovery. Two years after this, the people who had his papers found the method; and it was thence before the king of Poland and a great company of nobility at Dresden, and the secret purchased at a very considerable price. After this the time person carried the invention to Paris and many other places, and practised it every where with success.

The secret was this: a wooden vessel was provided holding a very considerable quantity of water. In the centre of this there was a case made of iron plates, and filled with gun-powder; from this vessel to the head of the larger vessel containing the water, there proceeded a tube or pipe, which might convey the fire very readily through the water to the gun-powder contained in the inner vessel. This tube was filled with a preparation of soft flaxen fibre, and quickly burning away; and the manner of using the engine was to convey it into the room or building where the fire was, with the powder in the tube lighted. The consequence of this was, that the powder in the inner case took fire, and, with a great explosion, burst the vessel to pieces, and dispersed the water every way; thus was the fire put out in an instant, though the room was flaming before in all parts at once. The advantage of this invention was, that at a small expense, and with the help of a few people, a fire in its beginning might be extinguished; but the thing was not so general as it was as first expected that it would prove; for though of certain efficacy in a chamber or close building where a fire had but newly begun; yet when the mischief had increased so far, that the house was filled in, or the top open, the machine had no effect. This was the contrivance first discovered by Grey, and from which our chemist Godfrey took the hint of the machine, which he called the **WATER-AND**, and would have brought into use in England. *Act. Eruditor.* ann. 1721, p. 183. Dr. Hales proposes to check the progress of fire by covering the floors of the adjoining houses with earth. The proposal is founded on an experiment which he made with a fir board, half an inch thick, part of which he covered with an inch depth of damp garden mould; and then lighted a fire on the surface of the mould; though the fire was kept up by blowing, it was two hours before the board was burnt through, and the earth prevented it from flaming. The thicker the earth is laid on the floors, the better; however, Dr. Hales apprehends, that the depth of an inch will generally be sufficient; and he recommends to lay a deeper covering on the stairs, because the fire commonly ascends by them with the greatest velocity. *Philol. Trans.* vol. XII, p. 174, p. 277. Mr. Hartley made several trials in the years 1775 and 1776, in order to evince the efficacy of a method which he had invented for restraining the spread of fire in buildings.

ings. For this purpose thin iron plates are well nailed to the tops of the joists, &c. the edges of the plates and ends being lapped over, soldered together, and hammered close. Partitions, flairs, and floors, may be defended in the same manner, and plates applied to one side have been found sufficient. These plans are so thin as not to prevent the floor from being nailed in the joints in the same manner as if this preventive were not used; they are kept from rust by being painted or varnished with oil and turpentine. The expense of the addition, when executed through a well building, is estimated at about five per cent. Mr. Hartley has a patent for this invention, and parliament has voted a sum of money towards defraying the expense of his numerous experiments.

14 Gen. III. cap. 38. The same preventive may also be applied to ships, fire-works, &c.

Lord Mahon has also discovered and published a very simple and effectual method of securing every kind of building against all danger of fire. This method he has divided into three parts, viz. under-scoring, carbazetting, and inter-securing. The method of under-scoring is either single or double; in single under-scoring, a common thick layer of oak or fir, about one-fourth of an inch thick, should be nailed against each side of every joist, and of every main member, supporting the floor which is to be secured. Other similar layers are then to be nailed along the whole length of the joists, with their ends butting against each other. The top of each of these layers or fillets ought to be at 12 inch below the top of the joists or timbers against which they are nailed; and they will thus form a sort of small ledge on each side of all the joists. These fillets are to be well bedded in a rough plaster, as is also mentioned, when they are nailed in, so that there may be no interval between them and the joists; and the same plaster ought to be spread with a trowel upon the tops of all the fillets, and along the sides of that part of the joists which is between the top of the fillets and the upper edge of the joists. In order to fill up the intervals between the joists that support the floor, short pieces of common lath, whose length is equal to the width of these intervals, should be laid in the contrary direction to the joists, and close together in a row, so as to touch one another; their ends must rest upon the fillets, and they ought to be well bedded in the rough plaster, but are not to be fastened with nails. They must then be covered with one thick coat of the rough plaster, which is to be spread over them to the level of the tops of the joists; and in a day or two this plaster should be trodden over, close to the sides of the joists, without covering the tops of the joists with it. In the method of double-scoring, the fillets and short pieces of lath are applied in the manner already described; but the coat of rough plaster ought to be little more than half as thick as that in the former method. While this rough plaster is laid on, some more of the short pieces of lath, above mentioned, must be laid in the intervals between the joists upon the first coat, and be dipped therein &c. They should be laid so close as to be close to each other, and in the same direction with the first layer of short lath. Over this second layer of short lath there must be spread another coat of rough plaster, which should be smoothed level with the tops of the joists, without filling above them. The rough plaster may be made of coarse lime and hair, or instead of hair, hay chopped to about three inches in length may be substituted with advantage. One measure of common rough sand, two measures of stacked lime, and three measures of chopped hay, will form in general a very good proportion, when fully mixed beat up together in the manner of common mortar. The lath should be put in after the two other ingredients are well beat up together with water. This plaster should be made full; and when the flooring boards are required to be laid down very soon, a fourth or fifth part of quick-lime in powder, formed by dropping a small quantity of water on the lime-fine a little while before it is used, and well mixed with this rough plaster, will cause it to dry very fast. If any cracks appear in the rough plaster work, near the joists, when it is thoroughly dry, they ought to be closed by washing them over with a brush wet with mortar wash: this wash may be prepared by putting two measures of quick-lime, and one of common sand in a pail, and stirring the mixture with water till the water becomes of the consistency of a thin jelly.

Before the flooring boards are laid, a small quantity of very dry common sand should be thrown over the plaster-work, and struck smooth with an hollow rule, moved in the direction of the joists, so that it may be running between each pair of joists. The plaster-work and sand should be perfectly dry before the boards are laid for fear of the dry rot. The method of under-scoring may be successfully applied to a wooden stair-case, but no

found it to be laid open the rough plaster-work. The method of extra-lathing may be applied to ceiling joists, to sloping roofs, and to wooden partitions.

The third method, which is that of inter-securing, is very similar to that of under-scoring; but no sand is inter-posed to be laid upon it. Inter-securing is applicable to the same parts of a building as the method of extra-lathing, but it is seldom needed.

Lord Mahon has made several experiments in order to demonstrate the efficacy of these methods. In most instances, it is only necessary to locate the floors, and the expense of under-scoring, including all materials, is only about nine pence per square yard; and with the use of quick-lime a little more. The extra expense of the method of extra-lathing is no more than six pence per square yard, for the timber above all and partitions; but for the ceiling, about nine pence per square yard. But in most houses no extra-lathing is necessary. Phil. Trans. vol. xxviii. for 1755, part ii. art. 40. p. 884, &c.

Fire-flies, in Ichthyology. See PASTINACA marina.

Fire-flies, in the history of Insects. Among the flies of Guiana, there are two species of *fire-flies*. The largest is more than one inch in length, having a very large head, connected with the body by a joint of a particular structure, with which, at some times, it makes a loud knock, especially when laid on its back. This fly has two feet, or horns, two wings, and six legs. Under its belly is a circular patch, which, in the dark, flames like a candle; and on each side of the head, near the eyes, is a prominent, globular, luminous body, in size about one-third larger than a mustard seed. Each of these bodies is like a shining star, emitting a bright and not small light; since two or three of these animals, put into a glass vessel, afford light sufficient to read without difficulty, when placed close to a book. When the fly is dead, these bodies will still afford considerable light, though less vivid than before; and if bruised, and rubbed over the hands and face, they become luminous in the dark, like a board smeared with phosphorus. They have a reddish brown colour, and live in rotten trees in the day, but are always abroad in the night. The other kind are not more than half as large as the former, and their light proceeds from under their wings, and is seen only when they are elevated, like jets of fire, appearing and disappearing every second. Of these the air is full in the night, though they are never seen in the day. They are common, not only in the southern, but northern parts of America, during the summer.

Fire-jack, or FRANK, a small gun, which fires with a flint and steel. It is distinguished from an old mallet or match-lock, which was fired with a match. The *fire-jack* is now in common use with the European armies, and carried by the foot soldiers. It is three feet eight inches in the barrel; and, including the lock, four feet eight inches, and carries a leaden bullet, of which twenty-nine make up. Its diameter is the fifty-five hundredths of an inch, and that of the barrel, one and a fifth part of the bore. *Fire-jacks* were made use of in a rage, when match-locks were disused; but the time of their invention is uncertain.

For the use of the *fire-jack*, see FRANK.

Fire-works, in art. *Fire of Artillery*, is an effect who gives the discharge, and the preparation of this occasion for all the compositions of *fire-works*, whether for service in war, or for rejoicings and recreations. He has a name to assist him.

His orders are given to the *fire-works* and bombardiers, who are obliged to execute them.

Fire-officer, an office of insurance from *fire*. See INSURANCE.

Fire-wood. See CORDAGE.

Fire-philosophy, or *Pyrology*, is a natural sect of philosophers who appeared towards the close of the sixteenth century, and made a figure in almost all the countries of Europe. The distinguishing tenet from which they derived this appellation was, that the intimate essences of natural things were only to be known by the trying efforts of *fire*, directed in a chemical process. They were also called *Theophrastus*, from their decrying against human reason as a dangerous and deceitful guide, and representing a divine and supernatural illumination as the only means of arriving at truth; they were likewise denominated *Pyrologists*, from the name of Pyrocellus, the eminent physician and chemist, who was the chief ornament and leader of this sect in Italy. It was patronized in England by M. Robert Flood or Fludd, who endeavoured to illustrate the philosophy of Pyrocellus in a great number of treatises; in France, it was zealously propagated by Rivier; in Denmark, to Severinus; in Germany, by Kunrath; an eminent physician of Dresden; and in other countries by warm and forceful votaries, who assumed a thinking air of piety and devotion,

devotion, and proposed to themselves no other end than the advancement of the Divine glory, and the restoration of peace and concord in a divided church; accordingly they were joined by several persons eminent for their piety, and distinguished by their zeal for the advancement of true religion. One of the most celebrated of these was Daniel Hoffmann, professor of divinity in the university of Helmstedt, who, availing himself of some unguarded passages in the writings of Luther, extravagantly maintained, that philosophy was the mortal enemy of religion; that truth was divisible into two branches, the philosophical and theological; and that what was true in philosophy was false in theology. Hoffmann was afterwards obliged, by the interposition of Henry Julius, duke of Brunswick, to retract his invectives against philosophy, and to acknowledge in the most open manner the harmony and union of sound philosophy with true and genuine theology. Mosheim's Eccl. Hist. by Macken, vol. iv. p. 17, 18. 8vo. edit. 1768.

FIRE-PLACES are contrivances for communicating heat to rooms, and also for answering various purposes of art and manufacture. For the latter kind, see **FORGE**, and **STOVE**.

The principal objects with regard to the former are lessening the charge of fuel and augmenting the benefit of *fire*. The general properties of air and *fire*, on which their construction chiefly depends, are the following, viz. that air is rarefied by heat, and condensed by cold; i. e. the same quantity of air takes up more space when warm than when cold; air rarefied and expanded by heat is specifically lighter than it was before, and will rise in other air of greater density; so that a *fire* being made in any CHIMNEY, the air over the *fire* is rarefied by the heat, becomes lighter, and immediately rises in the funnel, and goes out; the other air in the room, flowing towards the chimney, supplies its place, is rarefied in its turn, and rises likewise; and the place of the air thus carried out of the room, is supplied by fresh air coming in through doors and windows, or, if they be shut, through every crevice with violence; or if the avenues to the room be so closed up, that no fresh supply of air can be obtained, the current up the funnel must flag; and the smoke, no longer driven up, float about in the room. Common *fire* throws out light, heat, and smoke; the light and heat move in right lines with great swiftness, but the smoke is but just separated from the fuel, and moves only as it is carried off by the stream of rarefied air; and without a continual accession of air, will remain crowded about the *fire*, and fill it. Heat may be separated from the smoke and light by means of a plate of iron; and the greatest sensible heat is directly over the *fire*, where, besides the rays of heat shot upwards, there is a continual rising stream of hot air, heated by those rays that are shot round on every side.

The *fire-places* most in use are, 1. The large open *fire-places*, that were commonly used in former times, and are still continued in the country, and in kitchens. These require a large funnel, consume a great quantity of fuel, generally smoke, if the door be not left open, and contribute little to warm a room. Their spaciousness is their greatest convenience.

2. Instead of these old-fashioned chimneys, the modern *fire-places*, especially in towns, have been constructed with low breasts and hearths, narrowed by jambs. *Fire-places* of this contracted form will keep rooms generally free from smoke; but the funnel requires a considerable quantity of air, which rushes in at every crevice, so as to render the situation of persons continually exposed to it uncomfortable and dangerous. Many of the diseases proceeding from colds may be ascribed to strong drawing chimneys, whereby, in severe weather, persons are scorched before, while they are froze behind. These *fire-places* are of little use in warming a room; because the air round them, which is warmed by the direct rays of the *fire*, does not continue in the room, but is continually collected into the chimney by the current of cold air coming behind it, and is presently carried off. Besides, the greatest part of the *fire* is lost, being absorbed by the back jambs and hearth, which are so dark and porous as to reflect very little, and the upright heat lies directly up the chimney. To remedy this inconvenience the Sieur Gauger, in his book entitled *La Mécanique de Feu*, published in 1709, and since translated by Dr. Desaguliers (see CHIMNEY), proposed seven different contrivances of, 3. A third sort of chimneys, in which there are hollow cavities made by iron plates in the back, jambs, and hearth, through which plates the heat passing, warms the air in those cavities, which is continually coming into the room fresh and warm. This construction had many obvious advantages; but the expense and difficulty attending it discouraged the propagation of the invention. However, the upright heat was

almost wholly lost in these as in the common chimneys. 4. Another kind of *fire-place* is the Holland iron stove, with a flue proceeding from the top, and a small iron door opening into the room. These serve to warm a room, save fuel, and produce a constant change of air; but the *fire* is not free, and little use can be made of it but as that of warming the room. It is therefore rarely used in England, except in some work-houses.

5. The German stove is composed of five iron plates screwed together, and fastened so that the fuel may be put into it from another room, or from the outside of the house. It is a kind of oven erected, its mouth being without, and body within the room that is to be warmed by it. This stove warms a room with little fuel, and is attended with no danger from the irruption of cold air; but the *fire* is not free, and there is no change of air in the room heated by it. For an account of the Chinese Stove, see KANG.

6. Another kind of contrivance for warming rooms is a charcoal *fire* kindled in pots and chafin dishes. This is chiefly used in the shops of handicraftsmen. But the superfluous fumes arising from the coals render this mode of giving heat disagreeable and dangerous, and in a close room sometimes fatal.

The ingenious Dr. Franklin, whose name we have had frequent occasion of recording in this work, having recognized the inconveniences and advantages of *fire-places* in common use, proposed a new contrivance for this purpose, called the Pennsylvania *fire-plate*. 1. This machine consists of a bottom-plate or hearth-plate (see *Tal. Mf. chimney*, fig. 6.) with a rising moulding before for a fender, two perforated ears F, G, for receiving two screw-plates; a long air-hole, *aa*, through which the outward air passes into an air-box; and three smoke-holes represented by dark squares in B, C, through which the smoke descends and passes away; besides double ledges for receiving between them the lower edges of the other plates. 2. A black plate without holes, and furnished with a pair of ledges to receive, 3. The two side-plates, each of which has a pair of ledges to receive the side-edges of the front plate, with a shoulder on which it rests, two pair of ledges to receive the side-edges of the two middle plates which form the air-box, and an oblong air-hole near the top, through which the air warmed in the box is discharged into the room, and a wing or bracket, as H, and a small hole, as I, for the axis of the register to turn in. See fig. 7. which represents one of these plates.

4. An air-box, composed of the two middle plate DE and FG, fig. 8. and 9. The flit has five thin ledges or partitions cast on it, the edges of which are received into so many pair of ledges cast in the other; the tops of all the cavities formed by these thin deep ledges are also covered by a ledge of the same form and depth cast with them; so that when the plates are put together, and the joints luted, there is no communication between the air-box and the smoke. In the winding passages of this box, fresh air is warmed as it passes into the room. 5. A front plate, which is anchored on the under flue, and ornamented with foliage, &c. 6. A top plate, with a pair of ears M, N, (fig. 10.) and a hole in the middle of the bottom plate, and perforated for the same purpose. It has also a pair of ledges running round the under flue to receive the top edges of the front, back, and side plates. The air-box does not reach up to the top-plate by 2½ inches.

All these plates are of cast iron; and when they are all in their proper places, they are bound firmly together by a pair of slender rods of wrought iron with screws, and the machine appears as in fig. 10. There are also two thin plates of wrought iron, viz. 7. The shutter, which is of such a length and breadth as to close well the opening of the *fire-plate*, and serving to blow up the *fire*, and to secure it in the night. It is raised or depressed by means of two brass knobs, and slides in a groove left between the foremost ledge of the side plates and the face of the front plate. 8. The register, which is placed between the back plate and air-box, and furnished with a key; so that it may be turned on its axis and made to lie in any position between level and upright. The operation of this machine, and the method of fixing it may be understood by observing the profile of the chimney and *fire-plate* in fig. 11. M is the mantle-piece or breast of the chimney; C the funnel; B the false back, made of brick-work in the chimney, four inches or more from the true back, from the top of which a closing is to be made over to the breast of the chimney, that no air may pass into the chimney except that which goes under the false back, and up behind it; E the true back of the chimney; T the top of the *fire-plate*; F the front of it; A the place where the *fire* is made; D the air-box; K the hole in the side plate, through which the warmed air is discharged out of the

box into the room; II the hollow, formed by removing some bricks from the hearth under the bottom plate filled with fresh air, entering at the passage I, and ascending into the air-box through the air-hole in the bottom plate near G, the partition in the hollow, designed to keep the air and smoke apart; P the passage under the false back, and part of the hearth for the smoke; and the arrows in the figure show the course of the smoke. The fire being made at A, the flame and smoke will ascend, strike the top T, and give it a considerable heat; the smoke will turn over the air-box, and descend between it and the back plate to the holes near G in the bottom plate, heating in its passage all the plates of the machine; it will then proceed under and behind the false back, and rise into the chimney. The air of the room contiguous to the several plates, and warmed by them, becomes specifically lighter than the other air in the room, and is obliged to rise; but, being prevented by the closure over the *fire-plates* from rising up the chimney, is forced out into the room, and rising by the mantle-piece to the ceiling, is again driven down gradually by the stream of newly-warmed air that follows; and thus the whole room becomes in a little time equally warmed. The air, also, warmed under the bottom plate and in the air-box, rises and comes out of the holes in the side plates, and thus warming, and continually changing the air of the room. In the closing of the chimney a square opening for a trap-door should be left open for the sweeper to go up; the door may be made of slate or tin, and is placed, that by turning up against the back of the chimney when open, it closes the vacancy behind the false back, and thence the foot that falls in sweeping out upon the hearth. It will also be convenient to have a small hole about five or six inches square, cut near the ceiling through into the funnel, and provided with a shutter, by occasionally opening which, the heated air of the room and smoke of tobacco, &c. may be carried off without incommencing the company. For a farther account of the manner of using this *fire-place*, the advantages attending it, answers to objection, and directions to the brick-layer in fixing it, the curious reader may consult Franklin's Letters and Papers on Philosophical Subjects, p. 284—316. edit. 1769.

FIRE-POTS, in the *Military Art*, are small earthen pots into which is put a grenade, filled with fine powder till the grenade be covered; and then the pot is covered with a piece of parchment, and two pieces of match laid across and lighted. This pot being thrown where it is designed to go to execution, breaks and fires the powder, and thereby fires the powder in the grenade, which ought to have no fuse, that its operation may be the quicker.

FIRE, resistant or retentive, is a fire from the artillery and small arms directed in a line parallel to the horizon, or to those parts of the works of a place that are defended.

FIRE, running, is when a rank or ranks of men drawn up fire one after another; or when the lines of an army are drawn out to fire on account of a victory; in which case each squadron or battalion takes it from that on its right, from the right of the first line to the left, and from the left to the right of the second line, &c.

FIRE-SHIPS, in the Navy, vessels charged with combustible materials or artificial *fire-works*; which having the wind of an enemy's ship, grapple her, and set her on fire.

It is observed by Amelton, in his History of Commerce, vol. I. p. 432, that some English vessels, filled with combustible matter, and sent among the Spanish ships composing the Invincible Armada in 1588, are said to have given rise to the terrible invention of *fire-ships*. However, Livy informs us, that the Rhodians had invented a kind of *fire-ships* which were used in junction with the Roman fleet in their engagement with the Syrians in the year before Christ 190: cauldrons of combustible and burning materials were hung out at their prow, so that none of the enemies' ships durst approach them: these fell on the enemies' gallees, struck their beaks into them, and at the same time set them on fire. Liv. lib. xxxvii. cap. 30. tom. iii. p. 732. Ed. Crevier.

There is nothing peculiar in the construction of a modern *fire-ship*, except the apparatus, by which the fire is instantly conveyed from one part to another, and from thence to the enemy: for this purpose the *fire-room*, in which the combustibles are inclosed, is built between decks, and extends from the bulk-head at the fore-castle to a bulk-head raised behind the main-mast. The train inclosed in this apartment is contained in a number of wooden troughs which intersect each other in different parts of the ship's length, being supported at proper distances by cross-pieces and transoms. On each side of the ship are cut out six or seven port-holes, in fire about fifteen by eighteen inches, with their lips opening downward, and close caulked up. Against each port is fixed an *iron-chamber*, which, when the ship is fired, blows

out the port-lid and lets out the flame. Under the main and fore-throats is fixed a wooden funnel, one end of which communicates with a *fire-barrel*, and designed to convey the flames to the flouds. Between the funnels, called also *fire-trunks*, are two scuttles or small holes in the upper deck, serving also to let out the flames. Both funnels and scuttles must be stopped with plugs, and have sail-cloth or canvas nailed over them, to prevent any accident happening from above to the combustibles below. The port-holes, funnels, and scuttles, serve not only to communicate the flames to the outside and upper works of the ship and her rigging, but likewise to open a passage for the inward air confined in the *fire-room*, so that it may expand itself without blowing up the decks. On each side of the bulk-head behind is cut a hole big enough to receive a trough of the same size as the others; leading troughs whose fore-end ends communicate with other troughs within the *fire-room*, extend obliquely from these openings to false-ports cut through the ship's side: the decks and troughs are well covered with melted rosin. When either of the leading-troughs is fired, the flame is immediately conveyed to the opposite side of the ship, and both sides burn together. The cabins of the lieutenant and master are behind the *fire-room*, one on the starboard and the other on the larboard side. The captain's cabin is separated from these by a bulk-head.

The stores for a *fire-ship* of 150 tons are 8 *fire-barrels*, 12 *iron-chambers*, 31 priming composition barrels, 1 quick-match barrel, 30 dipped curtains, 150 long reeds single dipped, 75 short reeds single dipped, 75 short reeds double dipped, 200 bays single dipped, and 24 *port-fire*.

The quantity of composition for preparing the stores of a *fire-ship* is exhibited in the following table:

	potre.	luph.	corn.	pow.	pitch.	sulph.	tell.	tar.	oil.
lb.	lb.	lb.	lb.	lb.	lb.	lb.	lb.	lb.	lb.
For 8 barrels,	0	0	50	450	0	80	0	0	0
For 24 dips priming composition,	175	140	250	0	21	0	0	0	28
For the curtains, bays, and reeds for the ship, and sulphur for fusing them,	0	200	0	250	175	20	25	0	0
Total,	175	140	350	800	196	130	25	25	28

For reeds for the barrels, 160lb. being one-fifth of the whole of the last article.

When all the stores are provided, they are disposed of in the following manner: four of the eight *fire-barrels* are placed under the four *fire-trunks*, and the other four between them, two on each side the *fire-scuttles*, where they are securely cleated to the deck. The longest reeds are put into the fore and aft troughs, and tied down; the shortest reeds are laid in the troughs athwart, and tied down also: the bays, dipped at one end, are tied fast to the troughs over the reeds, and the curtains are nailed up to the beams in equal quantities on each side of the *fire-room*. The remainder of the reeds is placed in a position nearly upright at all the angles of every square in the *fire-room*, and there tied down; and some of them are put round the *fire-barrels* and tied fast. The priming composition is strewed along all the troughs, and over the reeds and bays; then lay the quick-match two or three strands thick on the reeds, and about the *fire-barrels* and chambers, in order to communicate a general fire at once; let the plugs be taken out of the funnels and scuttles, the curtains covering the *fire-barrels* be cut and rolled back; and let the leading troughs be laid with four or five strands of quick-match, and also the communication-trough, so that the fire may be communicated to the whole at once. *Port-fire*, which burns about twelve minutes, are frequently used for firing the ship in preference to matches. When two fleets commence an engagement, those who have the care of the *fire-ships* prime and prepare their *fire-works*; and when they are ready for grapping, inform the admiral of it by a particular signal. Muller's System of Math. &c. vol. v. p. 99, &c. and Falconer's Mar. Dict.

FIRE-ROSE is a coarse, harsh, dusty *rose-flower*, of a moderately compact texture, of a pale greyish colour, nearly white, with a very slight greenish tinge. This flower is moderately hard and heavy, and slightly colours the hands: it is composed of a fine small angular grit, cemented by an earthy sparry matter, intermixed with numerous small spangles of a silvery mica: it will not strike fire with steel, and in the fire changes to a slight reddish hue. It is called also *Rhyssos-flora*, from the place whence it is chiefly brought; it bears the fire, and is much used for chimneys, hearths, ovens, stoves, &c. It does not bear the weather, and is therefore unfit for building.

FIRE-WATER, a name given to alkali. See IGNIS AGNIS.

FIRE,

FIRE, wild, is a kind of artificial or fictitious fire, which burns even under water, and that with greater violence than out of it.

It is composed of sulphur, naphtha, pitch, gum, and bitumen; and it is only extinguishable by vinegar, mixed with sand and urine, or by covering it with raw hides. Its motion or tendency is said to be contrary to that of natural fire, and always following the direction in which it is thrown, whether it be downwards, sideways, or otherwise.

The French call it *Greek fire*, or *feu Grec*, because first used by the Greeks about the year 660, as is observed by the Jesuit Petavius, on the authority of Nicetas, Theophanes, Cedrenus, &c.

The inventor, according to the same Jesuit, was an engineer of Heliopolis, in Syria, named Calinicus, who first applied it in the sea-fight commanded by Constantine Pogonates against the Saracens, near Cyzicus, in the Hellespont; and with such effect, that he burnt the whole fleet therewith, wherein there were thirty thousand men.

But others will have it of a much older date; and hold Marcus Gracchus the inventor; which opinion is supported by several passages, both in the Greek and Roman writers, which shew it to have been anciently used by both these nations in the wars. See Scaliger against Cardan.

Constantine's successors used it on divers occasions, with equal advantage, as himself; and what is remarkable enough is, that they were so happy as to keep the secret of the composition to themselves; so that no other nation knew it in the year 960.

Hugh, king of Burgundy, demanding ships of the emperor Leo for the siege of Freixo, desired likewise the *Greek fire*. Chozier, Hist. de Dauph.

F. Daniel gives us a good description of the *Greek fire*, in his account of the siege of Damietta, under St. Louis. Every body, says that author, was astonished with the *Greek fire* which the Turks then prepared; and the secret whereof is now lost. They threw it out of a kind of mortar; and sometimes shot it with an odd sort of cross bow, which was strongly bent by means of a handle, or winch, of much greater force than the bare arm. That thrown with the mortar sometimes appeared in the air of the size of a sun, with a long tail, and a noise like that of thunder. The French, by degrees, got the secret of extinguishing it; in which they succeeded several times.

FIRE-works, or artificial FIRES, are preparations made of gunpowder, sulphur, and other inflammable and combustible ingredients, used on occasion of public rejoicings, and other solemnities.

The principal of these are rockets, serpents, stars, hail, mines, bombs, garlands, letters, and other devices. See ROCKET, STAR, BOMB, &c.

The invention of *fire-works* is by M. Mahudel attributed to the Florentines and people of Sicily; who found out likewise the method of adding decorations to them of statues, with fire issuing from their eyes and mouths.

The art of preparing and managing *fire-works* is called **PIROTECHNY**.

The making or selling of *fire-works*, or squibs, or throwing them about in any street, is, on account of the danger that may ensue to any thatched or timber buildings, declared to be a common nuisance, by 9 & 10 W. III. cap. 7. and punished by a fine of 40s.

FIRE-works, are subordinate officers to the *fire-masters*, who command the bombardiers, and are second lieutenants to the royal regiment of artillery.

These receive the orders from the *fire-masters*, and see that the bombardiers execute them.

FIRING, in the Military Art, denotes the discharge of the fire-arms; and its object is to do the utmost execution to the enemy.

The present method of *firing* by platoons is said to have been invented by Gustavus Adolphus, and first used about the year 1618; the reason commonly given for this method is, that a constant fire may be always kept up. There are three different ways of platoon *firing*; viz. standing, advancing, and retreating. But previous to every kind of *firing*, each regiment or battalion must be told off in grand divisions, subdivisions, and platoons, exclusively of the grenadiers, which form two subdivisions, or four platoons of themselves. In *firing* standing, either by divisions or platoons, the first fire is from the division or platoon on the right; the second fire from the left; the third, from the right again; and so on alternately, till the *firing* comes to the centre platoon, which is generally called the colour platoon, and does not fire, remaining as a reserve for the colours. *Firing* advancing is performed in the same manner, with this addition, that before either division or platoon fires, it advances three paces forward. *Firing* retreating varies

from either of the former methods; for, before either division or platoon fires, if they are marching from the enemy, it must go to the right about, and *after firing*, to the left about again, and continue the retreat as slow and orderly as possible.

In *hedge-firing* the men are drawn up two deep, and in that order both ranks are to fire standing. Oblique *firing* is either to the right and left, or from the right and left to the centre, according to the situation of the object. The Prussians have a particular contrivance for this purpose; if they are to level to the right, the rear ranks of every platoon make two quick but small paces to the left, and the body of each soldier turns one eighth of a circle, and *vice versa*. *Parapet firing* depends on the nature of the parapet over which the men are to fire, and also upon that of the attack made to possess it. This method of *firing* is sometimes performed by single ranks stepping on the banquettes and *firing*; each man instantly handling his arms to the centre rank of the time file, and taking his back in the room of it; and the centre rank giving it to the rear to load, and forwarding the arms of the rear to the front rank; by which means the front rank men can fire six or seven rounds in a minute with exactness. *Parapet firing* may also be executed two deep, when the banquettes are three feet broad, or in field works, where no banquettes are made. *Square firing* is performed by a regiment or body of men drawn up in a hollow square, in which case each front is generally divided into four divisions or *files*, and the flanks of the square, being the weakest parts, are covered by four platoons of grenadiers. The first fire is from the right division of each face; the second from the left division of each face, &c. and the grenadiers make the last fire. *Street firing* is practised in two ways; either by making the division or platoon that has fired to wheel by half-rank to the right and left outwards from the centre, and to march in that order by half divisions down the flanks on each side of the column, and to draw up in the rear, and go on with their priming and loading, or, to make the division or platoon, *after firing*, to face to the right and left outwards from the centre, and one half rank to follow the other; and in that order to march in one centre file down on each side of the column into the rear, and there draw up as before.

FIRING-iron, in the Manège, is a piece of copper or iron, about a foot long, one end of which is made flat, and forged like a knife; the back of it being half an inch thick, and the fore edge about the fifth or sixth part of this. When the farrier has made his *firing-iron* red-hot in his forge, he applies the thinnest part to the horse's skin, and so gives the fire to the hams, or such places as stand in need of it.

FIRKIN, an English measure of capacity, for things liquid; containing the fourth part of the barrel.

The *firkin* of ale contains eight gallons; and that of beer, nine; two *firkins* of beer make the kilderkin; two kilderkins the barrel; and two barrels the hoghead.

The *firkins* of *scap* and *hutter* are on the footing of the *firkins* of ale; viz. a gallon per *firkin* less than that of beer.

FIRLOT, a dry measure used in Scotland. The *out firlo*, which contains 214 pints of that country, is 194 inches in diameter both at top and bottom, being of a perfectly cylindrical form, and in depth 74 inches. The *wheat firlo* contains about 221 cubical inches, and the *bailey firlo* 32 standard pints; whereby it appears that the Scotch *wheat firlo* exceeds the English bushel by 33 cubical inches.

FIRMAMENT, in the Ancient Astronomy, the eighth heaven, or sphere; being that wherein the fixed stars were supposed to be placed.

It is called the *eighth*, with respect to the seven heavens or spheres of the planets, which it surrounds.

It is supposed to have two motions; a diurnal motion, given it by the primum mobile, from east to west, about the poles of the ecliptic; and another opposite motion from west to east, which last it finishes, according to Tycho, in 25412 years; according to Ptolemy, in 86000; and according to Copernicus, in 25800; in which time the fixed stars return to the same precise points wherein they were at the beginning. This period is commonly called *Plato's year*, or the *great year*. See PLATO'S YEAR of the SQUIN.

In divers places of Scripture the word *firmament* is used for the middle region of the air. Many of the ancients allowed, with the moderns, that the *firmament* is a fluid matter; though they, who gave it the denomination of *firmament*, must have taken it for a solid one.

FIRMAN, in the East Indies, and particularly in the territories of the Great Mogul, is the passport, or permit, granted to foreign vessels, to trade within their jurisdiction.

FIRMNESS, FIRMITAS, in *Philosophy*, denotes the consistence of a body; or that state, wherein its sensible parts cohere, or are united together, so that the motion of one part induces a motion of the rest. In which sense, *firmness* stands opposed to fluidity.

Some authors confound *firmness* with density; as thinking the same state or property of body implied by both; or at least, that *firmness* follows density; but this is a mistake. For mercury, the denser body in nature excepting gold, is yet one of the most fluid; and even gold itself, with all its density, when fused, wants *firmness*, or cohesion.

Many of the Cartesian, and others, hold *firmness* to consist in the more quiet of the particles of the body, and their mutual immediate contact; arguing, that a separation of parts can only arise from some matter interposed between them, which is excluded by the notion of cohesiveness.

But the insufficiency of this hypothesis is evident: for mere knapsack rest has no force, either to act or resist; and consequently two particles only joined by rest and cohesiveness, would never cohere so as that a motion of the one should induce a motion of the other. This is obvious in the case of two grains of sand, which, however contiguous, and at rest, will never constitute a firm coherent body.

The *firmness* of bodies, then, depends on the connexion or cohesion of their particles. Now, the cause of cohesion, fit Isaac Newton, and his followers, hold to be an attractive force, inherent in bodies, which binds the small particles thereof together, exerting itself only at, or extremely near, the points of contact, and vanishing at greater distances.

The *firmness* of bodies, therefore, follows the laws of the cohesion of bodies.

Hence, *firmness* in all bodies must be as the surfaces and contact of the component parts: thus a body, whose parts are by their peculiar shapes capable of the greatest contacts, is most firm; and that, whose parts are capable of the least contact will be most soft.

In the former, the greatest requisite is to be as near to cubes as possible, and in the latter to spheres. And in the same manner are to be accounted for, not only all the intermediate degrees between the most firm, and the most soft bodies, but those different consistencies, which are distinguished by other names, as friable, tenacious, glutinous, and the like; for the greater are the solidities of the component parts of any body, in proportion to their surfaces, though that body, by the aptitude of the contacts, may be what we call very hard; yet it will be most friable or brittle. And where the surfaces of the component particles are much extended upon a small quantity of matter, the bodies they compose, though they may be light and soft, yet they will be tenacious or glutinous; for although the flexibility of their compounding parts admits of their easily changing of figure by any external force, yet by their touching one another in so many points, they are very difficultly separated.

The former in the case, in crystallized salts, resins, and the like; the latter in turpentine, gums, and all of that sort.

FIRM-ORE, a kind of LEAD-ORE.

FIRST MESS, in the *Ancient Astronomy*. See PRIMUM MESS.

FIRST FRUIT, ANNATES or PRIMICES, the profits of a benefice for the first year after avoidance. See ANNATES and PRIMICES.

The *first-fruits* were formerly estimated according to a rate or value made under the direction of pope Innocent IV. by Walter bishop of Norwich, in 38 Hen. III. and afterwards advanced in value by commission from pope Nicholas III. A. D. 1202, 20 Edw. I. which valuation of pope Nicholas is still preferred in the exchequer; and the tenths or decime were the tenth part of the annual profits of each living by the same valuation; claimed by the holy see on the authority of the precept recorded in Numb. xviii. 26. These papal usurpations were first introduced into this kingdom by Pandolph the pope's legate, during the reigns of king John and Henry III. in the fee of Norwich, and afterwards attempted to be made universal by the popes Clement V. and John XXII. about the beginning of the fourteenth century. These claims were often opposed by the English parliament; but they continued till the Reformation in the reign of Henry VIII. at which period it was computed, that in the compass of 50 years 800,000 ducats had been sent to Rome for *first-fruits* only. This revenue was annexed to the crown by 26 Hen. VIII. cap. 3. confirmed by 1 Edw. cap. 4. and a new value *beneficiorum* was then made, by which the clergy are at present rated. By these statutes all vicarages under ten pounds a year, and all rectories under ten marks, are discharged from the

payment of *first-fruits*; and if the incumbent lives but half a year, he shall pay only one quarter of his *first-fruits*; if one whole year, half of them; if a year and a half, three quarters; and if two years, the whole. By stat. 27 Hen. VIII. cap. 8. no tenths are due to be paid for the first year; and by other statutes of queen Anne, in the fifth and sixth years of her reign, if a benefice be under fifty pounds per annum, clear yearly value, it shall be discharged of the payment of *first-fruits* and tenths. Queen Anne granted her royal charter, confirmed by stat. 2 Ann. cap. 11. whereby the whole revenue of *first-fruits* and tenths is vested in trustees for ever, to form a perpetual fund for the augmentation of poor livings, usually called queen Anne's bounty. Blackst. Comm. vol. 1. p. 281, &c.

FIRST-FRUIT, OFFICE is kept in the Temple, under the direction of a vintner, receiver, and comptroller, and their deputies and clerks.

FIRUZINUS, a term that frequently occurs in some of the old writers on gems, and has been mistaken by many to mean a ruby brown; and by others, black; but these are not colours to be sought after among the gems, and yet it is to these that this epithet is usually applied. We find it used for a blue kind of jasper by some authors, the same with the jasper bores of Piny and Dioscorides, and by others for the sapphires, which some of the ancients, particularly Theophrastus, having called *jaspas*, that is, black in its deepest colour, authors have been led to suppose that this word stood for black; but as there are not, nor ever were any black sapphires, it is certain from this, as well as many other instances, that the ancients used this word, *jaspas*, for a deep blue, and in that sense *firuzinus* velis does signify the same thing; it being the azurine color of the ancients, or what we call sky-colour, or a fine blue; such as the colour of the finest sapphires.

FISANELLE, in *Ornithology*, a name given by the Venetians to a water-fowl of the columbus kind, called by authors the columbus major, or great diver. Its general weight is about a pound, its beak is two fingers breadth long, and all its feathers are downy, soft, and very thick set together; its head and neck are brown, and its back is blackish; its sides and belly brown, and its breast of a silver white; it has no tail, and its wing-feathers are black and white; its feet are not webbed, but the toes are all widened by membranes. It is very common in the markets of Italy. Ray's Ornith. p. 256.

FISC, FISCUS, in the *Civil Law*, the treasury of a prince, or state; or that to which all things due to the public do fall.

The word is derived from the Greek *phoros*, a great host, used when they went to market.

By the civil law, none but a sovereign prince has a right to have a *fisc*, or public treasury. See FISCARIUM.

FISCAL, something relating to the pecuniary interest of the king, the public, or a private person.

The emperor Adrian erected the office of *fiscal* advocate in the Roman empire.

FISCHERLIN, in *Ornithology*, a name given by many of the northern nations to a small species of the LARUS or GULL, called by Mr. Ray *larus piscator*, by Linnaeus *larus marinus*, and in English, the lesser sea-swallow. It is smaller than the common black-bird. Its bill is yellow, tipped with black; its forehead and cheeks white; from the eyes to the bill is a black line. Its wings are long and grey, its feet short and yellow, its breast and belly are white, and of an exquisite gloss, the crown of its head black, and its back grey. They are very common on our coasts, and feed on small fish; but as they are delicate birds, and incapable of bearing the inclemency of the weather on our shores during winter, they quit their breeding places at its approach, and do not return till spring. Ray's Ornithology, p. 209.

FISGUM, a name used by some for the fish commonly called *misgum*.

FISH, in *Natural History*, the fourth class of animals, including four orders, viz. *pisces*, *injurales*, *theriacis*, and *abdominales*, which comprehend forty-seven genera, and four hundred species, in the Linnaean system; the characters of which are, that they have either a naked or scaly body, that they have no feet, and always have fins. According to the new Arctian system, *fish* in general are divided into five distinct orders. The generality of *fish* have the tail placed perpendicularly, but a few of them have it horizontally. Of those which have the tail perpendicular, some have the rays of the fins bony; and these either have the gills covered with a membrane, containing several bones, or they have no such membrane; of those which have this membrane, with the bones over the gills, some have the rays, though bony, yet not pungent; these are called the *MACALOPTERYGII*, or the soft-finned *fish*. Others have them with the

rays prickly; these are the *ACANTHOPTERYGII*, or prickly-finned fish. Those which have no bones in the membrane over the gills, make only one genus, and are called the *BRANCHIOSTEGI*. The other kind, which have not bony, but cartilaginous rays in the fins, are called *CHONDROPTERYGII*. And finally, those fish which have the tail placed not perpendicularly, but horizontally, are called *ACIPESCI*.

Naturalists observe much wisdom and design in the structure of fishes, and their conformation to the element in which they are to reside.

Their bodies are clothed and guarded in the best manner with scales, &c. suitable to their respective circumstances, the dangers they are exposed to, and the motion and business they are to perform.

The centre of gravity is placed in the fittest part of the body for swimming; and their shape is the most commodious for making way through the water, and most agreeable to geometrical rules.

They have several parts peculiar to themselves; as fins, to balance and keep them upright. See *FIN*.

And an air-bladder, or swim, to enable them to rise and sink to any height and depth of water, at pleasure.

They have also gills or branchiae, whereby they respire, as land animals do by the lungs.

The tail is the instrument of progressive motion, and serves to row them forward.

Their eyes are peculiarly formed to enable them to correspond to all the convergencies and divergencies of rays, which they arise from the watery medium, and the refractions thereof, may occasion it, in which respect they bear a near resemblance to those of birds.

Fishes are distinguished into *sea*, or *salt-water* fish, *river* *marini*, as the whale, herring, mackerel, &c. *river*, or *fresh-water* fish, *fluviales*, as the pike, trout, &c. and *pond*, or *lake*-fish, as the carp, perch, &c. to which may be added others which abide indifferently in fresh water or salt, as salmon, thorn-fish, &c.

Aristotle, and after him Mr. Willoughby, more accurately distinguish fish into *osteiæ*, cartilagines, and *spinosi*.

The *osteiæ* are those whose tail is so placed, that when the fish is in its natural posture, it stands parallel to the horizon. By this situation of the tail, they are enabled to force themselves suddenly to the surface of the water to breathe, which they are frequently obliged to do. This species, like land-animals, breathe by means of lungs, being destitute of gills; for this purpose they have an orifice on the top of the head, through which also they eject water. They copulate also like quadrupeds, and conceive and bring forth their young, which they suckle with their milk. Many of these circumstances induced LINNÆUS to place this tribe among his *MAMMELIA*. The cartilaginous fish are those whose fins serving for swimming, are sustained by cartilages in the place of the bony rays, which support them in the other, and which have also cartilages in the whole body, instead of bones. They breathe through certain structures, generally placed on each side of the neck, but in some instances beneath, and in some above, and from one to seven in number on each part. Many of the cartilaginous fish are viviparous, being excluded from an egg, which is hatched within them; but some, as the sturgeon and others, are oviparous. This division comprehends the same genera to which LINNÆUS has given the name of *AMPHIBIA natantia*. These are the characters of the two first classes; and all those fish which have their fins supported by bony rays, which have their tails placed perpendicularly not horizontally, and which have bones, not cartilages in their bodies, are called the *spinosi* fish.

The true characters of these two great classes of fish, the *osteiæ* and cartilagines, are easily found; but the characters of the spinose kinds are to be sought for deeper, and do not offer themselves so readily. The multitude of these, and the great likeness between several of the different genera, render it no easy task to distinguish them one from another. Though it be a general rule that the general characters of fish are to be taken from their external parts, yet in cases where these external parts differ among themselves in number, figure, and proportion, it is necessary that the primary character of the genus should be taken from those parts which are the least variable of all others; and which are the most peculiar to the fish under consideration, and the least common to other genera. The utmost care and skill of the *ichthyologist* is necessary to the distinguishing of these characters; and on a first enquiry he will find, that those parts which seem at first most proper to found distinctions on, are in reality least of all. The figure of the fins and tail in fish might seem one of the most essential characters for a general distinction; yet a farther search

into their nature will show that they can be of no use at all in this sense. Almost all the species of the cyprinæ, a genus constituted on essential and invariable characters, and a truly natural one, have fins acute at the end, and have forked tails; yet had these been made characters of the genus, they would have excluded fish that are properly of it. Thus the tench and the carassius have both obtuse fins, and tails straight or plain, not forked at the end. There are indeed many natural genera of fish, in which the fins and tail are alike in all, as the perches, the mackerel, the conger. These allow the fins and tail as very good collateral circumstances of the distinction; but even these could not well be distinguished by such marks alone, as they are common to many other genera besides. The figure of the breast, the belly, and the back, and the whole figure of the body in regard to length and breadth, are all very obvious characters; but they are not essential enough to be of any use in the distinctions of the genera. The back in some of the cyprinæ is tubercle, as in the common bream; whereas in almost all the others it is only moderately convex. This fish adds the use of the figure of the back as a general character, since the bream notwithstanding this difference from the rest of the cyprinæ, is truly of that genus. The belly, in the far greater number of the cyprinæ, also is plane in the anterior part, and between the pectoral ventrals and the anus is raised into a ridge; but in the tench, the whole belly from the head to the tail is flat. And to this may be added, that the general figure of the body, as to length or breadth, is extremely different in the cyprinæ of various species, as witness the bream, the silurus, the rutilus, &c. some of which are properly flat, and others almost round.

The figure of the HEAD, the MOUTH, the EYES, the NOSE, and other parts belonging to the head, are very different from these variable parts; they are in general fixed and permanent; and are of the utmost consequence in the distinction, but as this figure is too common, and belongs to too many species equally, they are rather of use in distinguishing the orders, classes, and families of fish, than their genera. Thus the eluæ, the coti, the coronges, and leucopages, or authors, have a plain general resemblance in the form of their heads, and yet they are of very different genera.

The figure of the FINS is generally always the same in the same genus, and therefore may be made a good collateral circumstance in the distinction; but as the same form is common to the scales of many genera, it is impossible to bring them to any great use in constituting the characters of the genera. As to the situation of the external parts, as that of the eyes, nostrils, mouth, and anus, they are generally regular, and alike in all the species of the same genus, regard being had to the proportion; but as their situation, though alike in these genera, is not peculiar to each, the marks are too common to be used as distinctive characters for genera. The situation of the fins also is usually very regularly the same in all the species of the same genus; but the same objection lies against this as against the others, in regard to making general characters from it. The number of RAYS can be of no use in making characters of genera; for this very often varies in the same species in different individuals, as in the pike, salmon, &c.

In regard to the other external parts of fish, there are none which are found in all the spinose fish, and suffice in all the several genera, except those little bones which are found on each side in the membrane of the head, which covers the gills. These bones are found in almost all the fish that have any bones, though in some kinds the thickness of this membrane makes them less conspicuous than in others. The number of these bones is much more regularly and constantly the same in the same genera, than that of the fins, as we may find by many observations. There are four genera of the *cyprinæ*, *gobi*, *poey*, *poey*, and *poey*, have the number of the fins very various in the several species of each genus; but in all these genera the number of the bones in the membrane that covers the gills, is regularly the same in every species. All the *poey* have regularly seven bones on each side, and so on of the rest. All the *cyprinæ* have three of these bones on each side; all the *gobi* have six on each side; all the *poey* seven; all the *poey* eight; all the *poey* fourteen; and so of the rest. There are only two known genera of fish that do not agree in all the species in the number of these bones; these are the salmon and the congoni. In the first of these the number of the bones is in the several species ten, eleven, or twelve; and in the several species of the other, there are eight, nine, or ten, and sometimes but seven. It is an observation, however, worthy the naturalist's consideration, that nature has given this difference in the number of these bones in the several species only to those genera in which all the spe-

F I S

cies have such a strong external resemblance in all parts, that scarce any thing more than the facies externa was necessary for knowing that they belonged to one another; for beside that all the *Elemoni* and *Categori* have a membranous appendage resembling a fin on the hinder part of the back, the several species of each genus are to very remarkably like one another, that it is not easy to distinguish them in many cases.

As to the number of the fins on *fish*, there are a full number of genera which have all the same general number, as the *stipiti*, *lepti*, *eximii*, *sumi*, *fumii*, *ceci*, *effici*, *perfici*, *fructi*, *ziti*, *ziti*, and *galei*. The first all have seven fins, clothed with bony rays. The same number of seven fins, and those of the same kind, is common also to the several other genera; but on the contrary, though all the fishes of the same genus have constantly the same number of bones in the membrane that covers the gills, yet it is very rare that the different genera have the same number. The perch, the *galei*, the *amphibii*, and the *fumii*, have indeed all seven on each side. The *stipiti* and the *perfici* have each of them three on each side. The *lepti*, the *eximii*, &c. and the *ziti*, have each six; these, however, are generally so very different in their other characters, and in their *facies externa*, that there is not the least danger of their being confounded one with another.

From this it appears very evidently, that the number of these bristles in the *manducator frontalis*, affords the best and most efficient of all characters for the distinction of the genera of the cathartous and olescepterigions, or, bay-funnel fish. This however is not sufficient alone, though it is a great assistant in determining the genera; but in order to bring fish to their proper genera, it is necessary first, that all of the same genus should have the same number of bones in the gills; then, that they should have in the genera the same external form and figure; after this, that they must have the same function of the fins, provided that the number does not differ, which sometimes has been found to vary in species truly of the same genus; but in general it is, and ought to be, the same in all.

The situation of the teeth also should be the same, and this generally holds right in the different genera of *As*, all the species having in each natural genus the same order of teeth. After this, the foci are to be examined, and these ought to be of the same form, and to have the same situation. These are the circumstances necessary to be enquired into, in regard to the establishing of full and natural genera. If all these agree in all the species, and, beside this agreement, there be an analogy in the situation and form of the other internal and external parts, particularly in the stomach, and its appendices, in the lineæ, and in the air-bladder, they will remain no doubt of the genus established on such foundations being perfectly full and natural.

is not to be expected, however, that every one of these characters should be found regularly in every species of the same genus in the same perfection; some will show them more, others less, and others will want something of them. But the three grand things that are essential to the elements of the genus, are the same number of bones in the branchiostegial membrane, and the same general external face or figure, and the same situation of the fins. The other circumstances are additional and confirmative. Upon the whole it appears, that the number of certain parts is the first great foundation of general distinctions in fish; and that no one sort or general character can be so extensive as to take in the whole at once, but that the characters of fish essential but more numerous must be taken into consideration, as well as the whole series of ichthyological distinctions. Artels, Ichthyology. Wallaghy thinks it would be yet more proper to divide fish into such as breathe with lungs, and such as breathe with gills; and then to subdivide those that breathe with gills, not into cartilaginous and finny, but into *crispus* and *scorpius*.

The *weipon* can find that *treastie* with gills, he subdivides into *long*; such as the *galei* and *canes*, or sharks and dog-fish; and broad, such as the *pallinco*, *raja*, &c. the subdivisions of each whetseaf, he gives in his chapter of cartilaginous fish in general.

The *apartus* kind that breathe with gills are the most numerous; and these he subdivides into such as are what we usually call flat-fish; and such as swim with their back upright, or at right angles to the horizon.

The plain or flat-fish kind, called usually *plani spinosi*, are either *quadrai*, as the rhombi and passeri: or *longiusculi*, as the soleæ.

Such as swim with their backs erect, are either long and smooth, and without visible scales, as the eel-kind; or shorter and less smooth, and these have either but one pair of fins at their gills, or else another pair of fins also.

F I S

on their bellies, which latter kind he subdivides into two kinds. 1. Such as have *no prickly fins on their backs*, but soft and flexible ones. 2. Such as have *prickly fins* upon their backs.

Those *fish* which have only soft and flexible fins on their backs, may be divided into such as have *three, two, or but one* single fin there.

No *f3* but the allelli have *three* F185 on their backs.

Fish with ribs *for* on their backs are either the trutta-
ceous, trout kind; or the gobionites, loch, or gudgeon
kind.

Fish with but *one* *soft* back-fin are of three sorts. The first kind have one long continued fin, from head to tail, as the hippurus of Rondeletius, &c.

The second have their fins but short, and placed just in the middle of their back; and these are either *marine*, as the herring-kind; or *fluxionis*, as those which we call *leather-mouthed fish*: such as carp, trout, &c.

Fish which have prickly fins in their backs, are of two kinds. 1. Such as have two prickly fins in their backs; and in these the anterior radii of their fins are always prickly. 2. Such as have but one prickly fin there.

The northern countries abound in large and delicate *fib* even to the extremest degrees of cold. Scheffer, in his History of Lapland, gives us a wonderful account of the abundance and large size of the *fib* there.

The salmon grow to a larger size than we ever see them, and are caught in such abundance that the natives who pickle them sometimes export not less than thirteen thousand fish in a year; pike are very common, and grow to the length of six or seven feet, and a proportionable thickness.

The carp grows to an all length, and often considerably more; and trout, barble, gudgeons, and perch, grow to a proportionable size and fannels. The last of these ~~fish~~ have one thing very peculiar among them; they take the skins in water, and then stripping off the scales, they add fresh water, and boil the skins down till wholly dissolved; of this they make a very pure and beautiful sort of glue, which is not inferior in strength to our coarse and stinking kind.

The coming of certain kinds of *fish* in shoals and infinite multitudes, to certain coasts at certain times of the year, is a thing of great advantage to mankind, as it gives opportunities of taking them with great ease, and in vast quantities; but the reason of these periodical returns of the several kinds does not seem much understood, though a little observation would probably clear it up. There is a small infest common in many seas, but particularly plentiful on the coasts of Normandy in the months of June, July, and August. This is well described by Rondeletius, under the name of the *sea caterpillar*; and at this time of the year it is so frequent in the place before mentioned, that the whole surface of the water is covered with it as with a foam. This is the *season* of the year when the herrings come also in such prodigious shoals to those coasts. The fishermen complain much of their rashy vermin, which diminish their fisheries; but they do not consider that it is to these alone that their fisheries are owing; for it is evident, that the herrings feed on these creatures greedily, by the vast quantity found in all their stomachs, and it is highly probable, nay scarce to be doubted, that the reason of these *fish* coming up in such numbers is to feed on them; probably, if observation was made, the same would be found to be the case in all the other places where the herrings come in the same sort of plenty. The mackerel come down in the same numbers regularly at certain times of the year, and for the same sort of reason. This *fish* is an herb-eater, and is particularly fond of that sea-plant called by naturalists the narrow-leaved purple palmated sea-wrack; this grows in great abundance on the coasts of England, and many other places, and is in its greatest perfection in the beginning of the summer, though sometimes later than others, according to the severity or mildness of the winter.

At the whole occasion of their coming in, such quantities is to feed on this plant, and those who would ascend to it growing very would know when to expect the mackerel better than those who listen for himmer for the signal of them. The tunnies come at certain seasons to the coasts of Provence and Languedoc, in the time floods that herrings and mackerel do at other places. This seems to be on another occasion, the one called by the French the emperor, and by the time confounded with the sword-fish, is the great enemy of these two, and in summer is plentiful in those seas, that they find no way of saving themselves, but by flying to the shallow waters where the other cannot easily follow them; hence they frequent the shores. The mackerels come upon the coasts of Brittany, and making a considerable article of commerce for that province, are yet a stronger

proof of the natural means that bring *fish* in shoals to certain places, than any other. These *fish* evidently come for food and that not natural to the place, but prepared for them by the inhabitants.

The people of Brittany purchase from Norway the oil and entrails of all the large fish caught in the northern seas; this is of late years become a regular and considerable article of trade; they cut these in pieces, and freeze them in vast quantities over the whole surface of the sea along their coasts, at times when the winds do not fit to blow it off.

This always brings together the pilchards in as vast shoals, as the herrings or mackerel come in other places; and the fishermen catch them in such quantities, as to be able to supply all the maritime places in the neighbourhood with them at a small price. The salmon, a *fish* bred in rivers, yet going at certain times to the sea, is another of those *fish* which come up at times in vast shoals. See SALMON.

Small *fish* may very well be kept in glass-jars with fresh water; and those of prey are very fit to be tamed by this means.

Some of these creatures often have no other sustenance than the animalcula of the water they are put in. Phil. Trans. N^o 478. p. 26. See DART and RUFF.

Mr. Boyle speaks of a kind of *fish*, on the coast of Ireland, the hearts of which are found inverted. Works abridg. vol. i. p. 27.

In the Philosophical Transactions, N^o 493, sect. 1. we have a method of preparing Specimens of *fish*, by drying their skins, as practised by Dr. Gronovius.

FISH, Molt, of Aleppo, or *Siniperca kneri* of Linnaeus, is described by Dr. Russell as resembling, in its shape, the *Siniperca kneri*, and live it having 7 scales. The head and back are black; the lateral line runs quite from the head to the tail, on the middle of the side below which to the belly, the colour generally changes to a dark purple. The under part of the head is also of the same colour. The head is flat, and about five inches long; the body is round and near the tail becomes flat. The mouth is not large in proportion as that of the flounder; it has no tongue, and the structure of the mouth and palate agrees exactly with the description of that *fish*. A small cirrus arises on each side from the edge of the nostril, and two others twice as long, and much stronger, from the angles of the mouth. These are also four on the lower lip; the eyes are situated near the corner of the mouth; the branchiae are four on each side, with a double row of sharp points. Near the branchiae there are two fins, composed of seven radii; to the anterior part of which joint a pretty strong prickly bone. Above the anus are two smaller fins; a long fin extends from under the anus to the tail, and another from the neck along the back; neither of which join with the tail. This *fish* is found in the river Orontes, and in stagnant waters near it. The natives of Aleppo are plentifully supplied with it from November to March. The fish is red like beef, and of a rank taste, and esteemed unwholesome, though for want of better much used. Hist. Aleppo, p. 73.

FISH, with regard to commerce, is distinguished into *dry, pickled, green, and red.*

FISH, dry or salt, is that which is salted and dried either by the heat of the sun, or by fire. Such principally are the cod, stock-fish, herring, and pilchard. See COD FISHERY.

FISH, green, is that lately salted, and which yet remains moist; as green cod, &c.

FISH, pickled, is that boiled and steeped in a pickle made of salt, vinegar, &c. as salmon, cod, herring, mackerel, pilchard, anchovy, and others.

FISH, red, is some fresh *fish* broiled on the gridiron, then fried in oil of olives, and barrelled up with a proper liquor, as new olive oil, vinegar, salt, pepper, cloves, and laurel leaves, or other herbs. The best *fish* thus prepared are *herring* and *tunny*.

FISH, considered as a food makes a considerable article in the furniture of the table, and the breeding, feeding, catching, &c. thereof, make a peculiar art of no small moment in the economy of a gentleman's house and garden.

To this relate the ponds, flows, &c. described in their proper places. See POND, and STRAW, &c.

FISH, blowing of, is a practice similar to that of blowing flesh, poultry, and pigs, and adopted for the same deceitful purposes. The method of blowing *fish*, especially cod and whiting, is by placing the end of a quill or tobacco-pipe at the vent, and pricking a hole with a pin under the fin which is next the gill; thereby making the *fish* appear to the eye large and full, which when dressed will be bony, and little else than skin and bones. But this imposition may be discovered by placing the finger

and slumb on each side of the vent, and squeezing it hard; the wind may be perceived to go out, the skin will fall in, and the *fish* appear bony and of little value.

FISH, breeding of. See FISH-POND.

FISH, castration of, is a method first practised by Mr. Tull, in order to prevent the excessive increase of *fish* in some of his ponds, where the numbers did not permit any of them to grow to an advantage as size. But he afterwards found, that the castrated *fish* grew much larger than their usual size, were more fat, and always in season. This operation may be performed both on male and female *fish*; and the most eligible time for it is when the ovaries of the female have their *ova* in them, and when the vessels of the male, analogous to these, have their seminal matter in them; because, at this time, these vessels are more easily distinguished from the ureters, which convey the urine from the kidneys into the bladder, and are situated near the seminal vessels on each side of the spine; which, without sufficient attention may be mistaken for the ovaries, especially when the latter are empty. The time least proper for this operation, is just after they have spawned, because the fish are then too weak and languid to bear with success, so severe an operation; however, with skill and care, it may be performed almost at any time. When a *fish* is to be castrated, it must be held in a wet cloth, with its belly upwards; then with a sharp pen-knife, having its point bent backwards, the operator cuts through the integuments of the rim of the belly, taking care not to wound any of the intestines. As soon as a small aperture is made, he carefully inserts a hooked pen-knife, and with this dilates this aperture from between the two fore-fins, almost to the anus. He then, with two small blunt silver-hooks, five or six inches long, and of this form *p*, by the help of an assistant, holds open the belly of the *fish*; and, with a spoon or spatula, removes carefully the intestines from one side. When these are removed, you see the uterus, a small vessel, nearly in the direction of the spine, and also the ovary, a larger vessel, lying before it, nearer the integuments of the belly. The last vessel is taken up with a hook of the same kind with those before mentioned, and, after detaching it from the side far enough for the purpose, divided transversely with a pair of sharp scissors, care being taken, that the intestines are not wounded or injured. After one of the ovaries has been divided, the operator proceeds to divide the other in the same manner; and then the divided integuments of the belly are sewed with silk, the stitches being inserted at a small distance from one another. Mr. Tull observes farther, that the spawning time is very various; that trout are full about Christmas; perch in February; pikes in March, and carp and tench in May; and that allowance must be made for climates and situation, with regard to the spawning of *fish*. When the *fish* are castrated, they are put into the water where they are intended to continue; and they take their chance in common with other *fish*, as though they were not castrated. With tolerable care, few die of the operation. Phil. Trans. vol. xxi. part ii. art. 106.

FISH, eye of. See EYES.

FISH, fecundity of, has been taken notice of by various writers, who have furnished instances of it in some particular species that have been thought surprising. Mr. Petit is said to have found in the carp 347,144 eggs; and Lewenhoeck in a cod of middling size 9,354,000. But Mr. Harmer has lately pursued the investigation of this curious subject with peculiar attention and accuracy, and extended his enquiries to a greater variety of species than any other person. The method which he adopted was that of weighing the whole spawn very exactly; he then took a piece weighing a certain number of grains, and carefully counted the eggs contained in it; and by dividing the number of eggs by the number of grains, he found, nearly, how many eggs there were in each grain. His computation of the number of eggs extended no farther than to those which he could distinguish with his naked eye; though by this limitation, he omitted many eggs, discoverable by a microscope, this might justly have been counted. The weights he used were avoirdupois, and be reckoned 437 1/2 grains to an ounce.

The following table exhibits the general result of his enquiries: the first column contains the names of the *fish* which he examined; the second, their weight; the third, the weight of their spawn; and the fourth their fecundity; and the fifth the time of the year, when each species of *fish* was examined. He has also added other columns, exhibiting the portion of spawn weighed, and the number of eggs found in a grain, and the result of examining several varieties of the same species of *fish*, of different weights, which the curious reader may consult. See Phil. Trans. vol. lvi. for 1767, art. 30. p. 280.

Tench	40 0		38152	May 28.

* N. B. Part of the spawn of this fish was accidentally lost, and therefore this number is considerably too small.

FISH, feeding of. 1. In a stew, thirty or forty carps may be kept from October to March, without feeding; and by filling with trawls, or haws, in March or April, you may take from your great waters, to recruit the stew; but you must not fail to feed all summer, from March to October again, as constantly as cooped chickens are fed, and it will turn to as good an account.

2. The constancy and regularity of feeding the fish conduces very much to their well-being, and thriving. The care of doing this, is best committed to the gardener, who is always at hand, and on the spot.

3. Any sort of grain boiled is good to feed with, especially peas and malt, coarse ground; the grains after brewing, while fresh and sweet, are also very proper; but one bushel of malt, not brewed, will go as far as two of grains; chippings of bread, and bits of a table, steeped in tepid droppings of strong beer, or played excellent food for carps. Of these the quantity of two quarts to thirty carps, every day, is sufficient; and to be fed morning and evening, is better than once a day.

There is a sort of food for fish, that may be called accidental, and is no less improving than the best that can be provided; and this is when the pools happen to receive the wash of commons, where many sheep have pasture, the water is thus enriched by the soil, and will feed a much greater number of carps than otherwise it would do; and further, the dung that falls from cattle standing in water in hot weather, is also a very great nourishment to fish. See farther on the method of feeding carps, and the advantages resulting from it, under the article CARP.

The best food, to raise pikes to an extraordinary fatness, is eels; and without them it is not to be done, but in a long time. Setting these aside, small perches are the best meat. Breams put into a pike pond breed exceedingly, and are fit to maintain pikes; which will take care they do not increase overmuch; the numerous fry of roaches and rudds, which come from the greater pools into the pike quaters, will likewise be good diet for them.

Fish in all streams, and carps in hungry springing waters, being fed at certain times, will come up and take their meat almost from your hand.

The best feeding place is toward the mouth of the pond, at the depth of about half a yard; for by that means the deep will be kept clean and neat; the meat thrown into the water, without other trouble, will be picked up by the fish, and nothing will be lost; yet there are several devices for giving them food, especially peas, as a square board like a trencher, supported by four strings, one at each corner, with leads at the bottom for sinking it, on which the food may be let down into the water.

When fish are fed in the larger pools or ponds, where their numbers are great, most boiled, or fresh grains, is the best food. Thus carps may be fed and raised like capons, and vench will feed as well; but perch are not for a stew in feeding-time.

FISH, generation of. The general opinion of the world as to the generation of fish, is, that the female deposits her spawn or eggs; and that the male after this ejects the sperm or male semen upon it in the water, by which it is fecundated. The want of the organs of generation in fish, gives an apparent probability to this; but Linnæus is greatly against it. He affirms that there can be no possibility of the impregnation of the eggs of any animal out of its body.

To confirm this, the general course of nature not only in birds, quadrupeds, and insects, but even the vegetable world, has been called in to his assistance, as proving, that all impregnation is performed, whilst the ova are in the body of the parent; and he supplies the want of the

FIS

organs of generation by a very strange process, affirming that the males eject their semen always, some days before the females deposit their ova or spawn, and that the females swallow this, and have their eggs by that means impregnated by it.

He says, that he has often seen three or four females at this time frequently gathered about the male, and greedily snatching up into their mouths the semen he ejects; he mentions some of the effects, some perch, and some of the cyprinids, in which he notices this process. Mr. F. all asserts, that he has frequently seen fish in actual copulation; and that this is generally done before the ova arrive at maturity. Phil. Trans. vol. xlviii. part ii. art. 106. p. 273.

FISH, general name of. See GENERAL NAME.

FISH, gilding of. See GILDING.

FISH, hearing of. When the lapilli or bones in the heads of fish, which are truly their organs of hearing, are examined in the heads of the several kinds, it appears, that they differ from one another both in their structure and substance. For in the catenatus fish, whose skeletons are truly bony, and which in certain respects may be compared to truly ligamentous trees, both the os perostome, and the auditory organs, are in these in other animals, perfectly osseous or bony; whereas the catenatus fish, whose skeletons are elastic, and are cartilaginous rather than bony, may be compared to the herpetophyta, or tough fleshy fern-plants; and their os, instead of an os perostome, have juncumbent arches; but it is cartilaginous not bony, and the auditory bones are of a tartareous kind of substance, being friable, and easily crumbled to pieces. See EAR.

It has been a disputed point among the naturalists of many ages, whether fish hear or not; it is plain that the catenatus fish have all of their auditory passages or ear-holes, but it has not been found, that any other fish have any appearance of them. Many authors have been fond of believing that all fish have hearing; but their arguments in general are inconclusive.

Among the ancients, many authors appear to have been positive in the opinion, that fish had hearing, though they were by no means satisfied about the ways or passages by which they heard. Placemian after who discovered some bones in the head of the pike, which had very much the appearance of being organs of hearing, but he could never discover any external passages to them. Klein seems to be the only author who has improved upon this hint to any purpose; and he affirms and proves from experiments and observations, that all fish have the organs of hearing, and have also passages from without to those organs, though in many species they are difficult to be seen, and that even the most minute and obscure of these are capable of communicating a tremulous motion to those organs from sounds passing from without; nor does the water appear on serious consideration to be any impediment, but rather a proper medium for the conveying of the sounds to such organs; and it appears no way more strange, that they should hear through the water, than that a man should hear in one room the words pronounced in another, though there is a partition between them.

The organs of hearing in fish are indubitably the little bones commonly called lapilli, and found in the heads of all fish; these are constituent and essential parts in the head of fish, and are generated with the brain itself; not an accidental thing as some have believed them to be. They are always found to differ in magnitude according to the size of the fish they belong to; and they are more easily distinguished in the heads of the spinose fish, than in any other kind. There are in all kinds of fish three pairs of them; the first are the two largest bones, and are really enough found, but the greatest difficulty lies in discovering the other two pairs, which are small, and are enveloped in distinct little bags composed of a fine membrane. These seem to be the auditory organs, and to answer to the incus, malleus, andapes, in other animals; and by a diligent and careful inspection, the age of a fish may be determined by the number and thickness of the laminae and fibres of these bones, in the same manner as the age of a tree is known by the number of circles of the wood. The passages by which a tremulous motion is conveyed from without to these internal organs are to be discovered with care in most fish, and in particular in the pike; though Placemian could not discover them there. A close examination of the head of this fish will show several holes into which his bristles may be thrust, and these will be found to go directly into the internal auditory organs; and in dissecting the head of a sturgeon, the auditory duct is easily traced as far as the membranous body, in which the three pairs of little bones are placed. Curious figures of these auditory ducts, and of the great variety of their osseous

lapilli, are exhibited in Klein's History of Fish, to which we refer, as much more expeditious than any form of words can be. See an account of Klein's book in Phil. Trans. ser. vol. ix. p. 114, &c.
Mr. Baker ascribes to the exquisite sensibility of the organs of sight and feeling in fish those effects, which others have urged as arguments of their possessing the faculty of hearing, in Phil. Trans. vol. xiv. art. 4. p. 153. However, M. Camper has more lately endeavoured to show, that fish are really endowed with this sensation, and described the organs adapted to this purpose in some particular species. Mem. de Mathem. & Phys. Roy. Acad. Sc. Paris, vol. vi. 1774. And the abbe Nollet has long since evinced, by diving under water for this purpose, that water is capable of receiving and transmitting to the animals contained in it, those peculiar impressions that constitute sound. Mem. de l'Acad. 1743.

FISHERY, *in Zoology*. See SABLE.

FISHERY, a commodious place for fishing; or a place wherein great quantities of fish are caught.
The principal fisheries of Europe for salmon, herring, cod, and mackerel, are along the coasts of England, Scotland, and Ireland; for cod, on the banks of Newfoundland; for whales, about Greenland; for pearls, in the East and West Indies, &c.

FISHERY also denotes the commerce of fish; more especially the catching of them for sale. The fishery makes a principal branch of the British commerce. A great quantity of vessels and seamen are employed therein; and besides what is spent at home, large sums are yearly returned, merely for herring, cod, and pilchard, exported to Spain, Italy, and several parts of the Mediterranean, and the islands of the Archipelago.

Yet are our countrymen reproached, and with a good deal of justice, for their remissness in this branch of trade. The advantageous situation of our coasts might be of immense benefit to us, did not we let our neighbours over-reach us therein. The Dutch, French, Hamburgers, &c. come yearly in large fleets, and not only take the fish from our own coasts, but sell them to us for our money, when they have done.

Scotland suffers incredibly on this score: no country in Europe can pretend to rival it in the abundance of the finest fish, wherewith its numerous harbours, bays, rivers, &c. are stored. In the river Dee, it is said, an hundred and seventy head of salmon is not very extraordinary for a single draught of a net; and the pickled salmon sent hence is allowed the best in Europe. The Scottish islands, especially those on the western side, do certainly lie the most commodiously for carrying on the fishing-trade to perfection.

King Charles the first began the experiment in 1630 and 1631, in conjunction with a company of merchants; but the civil wars soon put it aside. King Charles the second, in 1661, made a like attempt; but having pressing occasion for money, he was persuaded to withdraw what he had employed in the fishery; at which the merchants, joined with him, being displeased, did the like themselves.

Since the Union, several efforts have been made to retrieve it; and in 1750 there was a corporation settled on that footing by parliament, called the *Free British Fishery*, for the term of twenty-one years, under the direction of a governor, president, vice-president, council, and other officers, who were empowered to make by-laws, &c. and to raise a capital of 500,000. and the Scotch fishery, encouraged by fishing chambers, erected in several cities, is likely to be put on a very advantageous basis. See *Herring FISHERY*.

Vol. II. N° 131.

FISHERY, *anchovy*. See ANCHOVY.

FISHERY, *cod*. The cod is a fish of passage, pretty large, with a great head, and teeth in the bottom of the throat; its flesh white; its skin brownish on the back, white under the belly, and covered with a few thin transparent scales. See COD.

It eats excellently when fresh: and, if well prepared and salted, will keep a long time. This fish, thus prepared, is commonly eaten among us in Lent, &c. under the denomination of *fish-fish*, or *fish-fish*. There are two kinds of *fish-fish*, the one called *green*, or *white*; and the other *dried*, or *cured*; though it is the same fish, only differently prepared.

They are also distinguished by the places from whence they are brought, as well as by the manner of curing, into Aberdeen-fish, Iceland-fish, green-fish, rock-fish, North-sea cod, poor Jack, and barrelled cod.

Green cod.—The chief fisheries for *green cod* are in the bay of Canada, on the Great and Little Banks, near the coast of Newfoundland, the Isle of St. Peter, and the Isle of Sable; and thither vessels are yearly sent from divers parts both of America and Europe.

The vessels used herein are from a hundred to a hundred and fifty tons burden; and these will bring thirty or thirty-five thousand fish a-piece.

The most essential articles in this fishery are the persons who know how to open the fish, to cut off the heads, and to salt them; upon the ability of which the success of the voyage chiefly depends.

Several authors will have it, that the Biscayans, in pursuing their whales, made the first discovery of the Great and Little Banks of *cod* at Newfoundland, Canada, &c. a hundred years before Columbus's time; and that it was a Biscayan Newfoundland that gave the first intimation thereof to Columbus.

Others say, that the Great Bank was discovered by a native of St. Malo's, named Carrier. But be the discoverer of what name or nation he may, the discovery is certainly highly valuable; there is not a trading nation in Europe, but allows the commerce of *cod-fish* one of the most secure and gainful that is known.

The best, largest, and finest *cod* are those taken on the south-side of the great Bank, which is a kind of submarine mountain, one hundred and fifty miles long, and fifty broad, and at the distance of twenty-five leagues from Newfoundland; those on the north-side are generally much smaller.

The best season is from the beginning of February to the end of April: at which time the *cod*, which during the winter had retired to the deepest part of the sea, return to the Bank, and grow very fat.

Those caught from March to June keep well enough; but those taken in July, August, and September, soon spoil. The fishing is sometimes done in a month, or six weeks; and sometimes it holds four or five months. At Lent *draws on*, if the fishermen have but half their cargo, they strive who shall make homeward the first; the market being then the best.

Some will thus make a second voyage, before others have got loading for the first. Each fisher only takes one *cod* at a time; and yet the more experienced will take from three hundred and fifty to four hundred *per day*; but this is the most; for it is very fatiguing work, both on account of the weight of the fish, and of the extreme cold which reigns on the Bank.

The wages usually allowed the captain and sailors, is one third of the *cod* they bring home found.

They salt the *cod* on board. The head being cut off, the belly opened, and the guts taken out, the fisher ranges them in the bottom of the vessel, head to tail; and having thus made a layer thereof, a fathom or two square, he covers it with salt; over this he lays another layer of fish, which he covers as before; and thus he disposes all the fish of that day, taking care never to mix the fish of different days together.

By that time the *cod* has lain thus to drain three or four days, they are moved into another part of the vessel, and salted afresh. After this, they are no more to be touched, till the vessel have its burden.

Sometimes they put them up in barrels, for the convenience of carriage.

Dry cod.—In the fishing of *dry cod*, vessels of all sizes are used; though such are generally chosen, as have large holds, because this sort of fish incumbers more than that burden.

As *cod* is only to be dried by the sun, the European vessels are obliged to put out in March, or April, to have the benefit of the summer for drying. Indeed, we send vessels for *cod* in June and July; but those only buy what had been fished and prepared by the inhabitants of the English colonies of Newfoundland, and the neighbouring parts; in exchange for which, we carry them meal, brandies, biscuits, pulse, melasses, linen, &c.

The principal fishery for dry cod is along the coast of Placentia, from Cape Roie, to the Bay des Espérs; in which compass there are direct commodious ports for the fish to be dried in.

The fish intended for this use, though of the same kind with the green cod, is yet much smaller; whence it is the fitter to keep, as the fish more easily penetrates it. The method of fishing is much the same in both; only this latter is the more expensive, as it takes up more time, and employs more hands; and yet scarce half so much salt is spent in this, as in the other.

When several fishing vessels meet, and intend to fish in the same port, he whose ship first touches ground, becomes entitled to the quality and privileges of ADMIRAL; he has the choice of his station, and the refusal of all the wood on the coast at his arrival.

As soon as the captains arrive, they unrig all their vessels, leaving nothing but the shrouds to sustain the masts; and in the mean time the mates provide a tent on shore, covered with branches of fir, and falls over them; with a scaffold, fifty or sixty feet long, and about one third in breadth.

While the scaffold is making ready, the crew are fishing; and as fast as they catch, they bring their fish, open them, and fall them on movable benches; but the main fishing is performed on the scaffold, called FLAKE.

When the fish have taken salt, they wash them; and to drain them again, lay them in piles on the galleries of the scaffold; when drained, they range them on hurdles, a fish thick, head against tail, with the back uppermost; observing, while they lie thus, to turn and shift them four times every twenty-four hours.

When they begin to dry, they lay them in heaps of ten or twelve a-piece, to retain their warmth, and continue to enlarge the heap every day, till it becomes double its first bulk; at length they join two of these heaps into one, which they turn every day, as before. Lastly, they salt them over again, beginning with those that had been salted first; and thus lay them in huge piles, as big as haystacks.

In this manner they rest, till they are carried a ship-board, where they are laid on branches of trees, disposed for that purpose in the bottom of the vessel, with mats all around to prevent their contracting any moisture.

There are four kinds of commodities drawn from cod; viz. the roe, and tongue, which are salted at the same time with the fish, and barrelled up; the roe, or eggs, which, being salted and barrelled up, serve to call into the sea, to draw fish together, and particularly pilchards; and lastly, the oil, which is used in dressing of leather, &c.

By the definitive treaty between Great Britain and France in 1763, the French are now absolutely deprived of the powerful fortifications of Cape Breton, and of the possession of Canada and all its dependencies; and are entitled to no possessions contiguous to Newfoundland; except the small islands of St. Peter's and Miquelon, ceded by the sixth article of the said treaty to his most Christian majesty, as a shelter for the French fishermen; and his most Christian majesty engages not to fortify the said islands, to erect no buildings upon them, but merely for the convenience of the fishery, and to keep upon them a guard only of fifty men for the police. And by the eighteenth article of the same treaty, it is expressly stipulated between Great Britain and Spain, that his Catholic majesty desists, as well for himself, as for his successors, from all pretensions which he may have formed in favour of the Guisquicoms and other his subjects, to the right of fishing in the neighbourhood of Newfoundland.

The Scots catch a small kind of cod on the coasts of Buchan, which is highly prized, though very much like ling. They salt it, and dry it in the sun, upon rocks; and sometimes in the chimney; but the greatest part of it is spent at home.

FISHERY, *cod.* See CORAL.

FISHERY, herring. The herring is a small salt-water fish, with a bluish back, and a white silver belly, not unlike a little shad-fish; whence it is called in Latin *alga minor*. Rondeletius calls it *heringus*.

It is a popular error to believe the herring to be the *hale* of the Romans. The *hale* was no particular fish, but a kind of sauce, made of any kind of salt-fish. The modern herring seems to have been unknown to the ancients: it is neither the *hale*, nor *hale*, nor *maris*, nor *loma*, nor the *gerres* of Pliny. See Rondelet. De Piscib. Maris. lib. v. cap. 15. and Vossius De Idolis. See HERRING.

Herrings are chiefly found in the North Sea. It is true, there are fisheries elsewhere, but none so copious. They usually make two fishing seasons for herrings; the first in June, July, and August; the second in autumn;

the latter of these is the more considerable, on account of the fog, which are very favourable to this kind of fishing.

It is commonly said, that nobody ever saw a herring alive, and that they die the minute they are taken out of the water; but there are instances to the contrary.

The herring is a fish of passage; so that it is allowed to catch them on holidays and Sundays in the Decretal there is an express chapter to this effect. They go chiefly in shoals and are fond of following any fire, or light; and in their passage they resemble a kind of lightning themselves.

About the beginning of June, a shoal of herrings, in bulk not less than the whole extent of Great Britain and Ireland, comes from the North, on the surface of the sea; and their approach is known to the Shetlanders by several tokens in the air and water, as by the birds, such as juncos, and others, which follow, to prey on them, and the smoothened of the water. It is not certainly known from whence they come; though it is probable that their winter rendezvous is within the Arctic circle, where the seas swarm with insect food in greater abundance than in our warmer latitudes. But when they arrive in these seas, they call their spawn; for they come to us full, and are fatten long before they leave us. As the great shoal formed by the migrating herrings, and divided into distinct columns, five or six miles in length, and three or four in breadth, reflecting in bright weather many splendid colours, passes between the Shores of Greenland and the North Cape, it is probably much straitened, and as it reaches the extremities of Great Britain, it is separated into two parts: one part flows west or south-west, and leaving the islands of Orkney and Shetland to the left, passes on towards Ireland; where being interrupted by that island, this part is again divided; some, keeping to the coast of Britain, go southward down St. George's or the Irish channel, and the others, edging off for want of room to the west and south-west, go along the Iberian ocean, and, keeping on the coast, reach the fourth shores of Ireland, from whence they flow southward, and join the rest in the Irish channel.

The other part of the first division made in the north, passing a little to the east and south-east, come down into the German ocean: they pass by Shetland, and make the point of Buchan, and the coast of Aberdeen, filling the bays, rivers, creeks, and with their innumerable multitudes. Hence they proceed southward, pass by Dunbar, and rounding the high shores of St. Abb's and Berwick, are seen again off Scarborough, and not before, but not in bulk, till they come to Yarmouth roads in England, and thence to the mouth of the Thames, from whence passing the British channel, they are seen no more in any number. The herrings are found again on the shores of North America, though not in such quantities as with us; and they are seen no farther south, than the rivers of Carolina. Whether these may be part of that large shoal, which, at their first coming by the coast of Greenland, keep to the coasts of America on the north-west side, or whether they are the remnant of those that pass our channels, is uncertain; but we know that they are not seen in quantities in any of the southern kingdoms, as Spain, Portugal, or the south parts of France, on the side of the ocean, or in the Mediterranean, or on the coast of Africa.

The Hollanders were the first who began the herring-fishery, and observed the several seasons of their passage. Their first regular fishing is fixed to the year 1104.

In the year 1313 we have an account of the seizure of a ship of Lynn, in the port of Bergen, which had been fishing on the Norway coast for herrings. Rymer's *Fœd.* vol. iii. p. 400. And as findings of herrings carried to a distance must have been salted, it is plain that salted herrings, either wet or else dried, called red herrings, were, in those times, a merchantable commodity in foreign parts. And in 1338 we have an account of fifty falls of herrings shipped from Portsmouth for the use of the army and fleet of Edward III. in Gascogne, which must have been salted, either wet or dried. *Fœd.* vol. v. p. 12. And they were barrelled and salted at the port of Whitby in Yorkshire, in 1304. *Fœd.* vol. vii. p. 778.

But the present method of pickling them was not discovered till the year 1416; though others date it from the year 1397. Willoughby, in his History of Fishes, observes, that Will. Beckles, or Beakel, an native of Bier Unet, rendered his name immortal by the discovery of the secret of curing and pickling herrings, which he might probably have learned from the people of Yarmouth, and other parts of England, where herrings were not only salted and dried for red-herrings, but salted and barrelled up wet, at different times, from the year 1360 to 1360. Yarmouth has indeed been long famous for its herring.

herring-fair, which was regulated by an act, commonly called the statute of *herring*, in the thirty-fifth year of Edward III. He adds, that the emperor Charles V. coming to the Low Countries, made a journey to the isle of Bier Ulic, with the queen of Hungary, on purpose to view the tomb of this first harrier of *herring*.

The Dutch begin their *herring-fishery* on the twenty-fourth of June, and employ no less than ten or eleven hundred vessels therein. These vessels are a kind of barks called *hulks*, carrying from forty-five to sixty ton, and two or three small canons.

Before the establishment of the Society of the Free British *Fishery*, the number of Dutch vessels employed in this *fishery* was more considerable, and amounted to fifteen hundred or two thousand.

None of them are allowed to fire out of port without a convoy, unless there be enough of them together, to make eighteen or twenty pieces of cannon; in which case they are allowed to go in company. Before they set out, they make a verbal convention; which has the same force, as it is in writing.

These regulations of the admiralty of Holland are partly followed by the French, and other nations; and partly improved and augmented with new ones; as, that no fisher shall cast his net within an hundred fathoms of another boat; that while the nets are cast, a light shall be kept on the hind part of the vessel; that when a boat is by any accident obliged to leave off fishing, the light shall be cast into the sea; that when the greater part of a fleet leaves off fishing, and casts anchor, the rest shall do the same, &c.

By the act for encouraging the British white *herring-fishery*, in 1750, it is required, that the boats employed in this *fishery*, entitled to the bounty of 30s. per ton, shall be decked vessels, built in Great Britain, after the commencement of the act; and that each of them shall carry twelve Winchester bullets of lead, for every last of fish which each vessel is capable of holding; and as many more new barrels as such a ship is capable of carrying; and two acres of tanned nets; i. e. every vessel of twenty tons shall have one last of nets, each thirty yards full on the top, and seventeen fathoms deep, and others in proportion; and be provided with one other fish of fish like nets, on board a jagger or tender, which is to attend the said *fishery*. Every such boat properly manned and furnished, shall proceed either to Bristol's Sound in Shetland, and be at the rendezvous of the said *fishery* there, on or before the eleventh day of June, but shall not shoot their net till the thirteenth, and shall continue following the shoal and fishing, as they move southward, to the first of October; or to Campheltown in Argyle-shire, and be at the rendezvous of the said *fishery* on or before the first day of December, unless they shall have sooner completed their loading of fish. For other regulations of the *herring-fishery*, see *HERRING*.

The manner of fishing has nothing particular in it. The nets wherein the fish is drawn, should, regularly, have their meshes an inch square, that none of the lesser fry may be taken.

The commerce of *herring*, both white, i. e. pickled, and red, is very considerable; but there are so many different sorts, prepared in such different ways, and different places, that it is hard to say any thing precise thereupon.

The white *herring* cured by the Dutch are in the greatest repute: they are distinguished into four kinds, according to their size. The goodness of this commodity consists in its being fat, fleshy, firm, white; salted the same day it is taken, and with good salt, and well barrelled.

The Irish *herring* are the next in value after those of Holland; and principally those of Dublin, which are scarce inferior to the best *herring* of Rotterdam or Euxysten. The Scotch *herring* is not so well prepared, gutted, salted, nor barrelled, as the Dutch; and yet its taste is excellent, that of those caught on the western coast especially; nor is it to be doubted, but that if the Scots were as careful in these circumstances as their neighbours, their *herring* would be the best in the world. The *herring* fished in England is inconsiderable; the fish being too dry for the market. However, at Yarmouth and Lowestoft they take and cure about 50,000 barrels of *red-herring* in a year; and very large quantities are also caught at the mouth of the Thames by the fishing smacks of London, Folkestone, Dover, Sandwich, &c. for the London markets, and sent the sea-coast of Kent and Sussex for general consumption.

Curing and preparing herring. 1. For white or pickled *herring*: as soon as the *herring* are taken out of the sea, one of the crew, appointed for this office, cuts them open, and takes out the guts, and every thing but the milts and roes, which are always to be left in the body of the fish. Then washing them in fresh water, they are left the space of twelve or fifteen hours in a tub full of strong brine made of fresh water, and sea salt.

When they are taken out, they drain them; and when well drained, put them up in barrels; taking care to dispose and range them evenly, in rows, or layers, pressing them well down, and strewing a layer of salt both at top and bottom.

When the barrel is full, they stop it up very close, that no air may get in, nor any brine out; either of which is very prejudicial to the fish.

The Dutch after opening and gutting the *herring*, cure and salt them by lining or rubbing their insides with salt; they are then packed, with handfuls of salt between each row, and stopped up close.

2. For *red-herring*: the fish being caught, they proceed to wash, gut, and lay them in brine, as for *pickled-herring*; only they let them lie double the time in brine, viz. twenty-four hours; inasmuch as they are to take all their salt here, whereas the other kind takes half its salt in the barrel.

When the *herring* are taken out of the brine, they spit them, i. e. fling them by the head on little wooden spits, and thus hang them in a kind of chimney, made for the purpose; and when the chimney is as full as it will hold, which less than ten or twelve thousand seldom effect, they make a little fire underneath of brush-wood, which yields a deal of smoke, but no flame.

Here the *herring* remain, till sufficiently smoked and dried; which ordinarily is in twenty-four hours. Then they are taken down, and barrelled up for keeping.

Their goodness consists in being large, fleshy, fat, oily, soft, and pliable; their outside of a yellow, golden colour; their having roes, or milts, within them, and being well salted and barrelled. See *HERRING*.

FISHERY, herring. *Lobster* are taken along the British channel, and on the coast of Norway, whence they are brought to London for sale; and also in the frith of Edinburgh, and on the coast of Northumberland.

By 10 and 11 W. III. cap. 24. no *lobster* is to be taken under eight inches in length, from the peak of the nose to the end of the middle fin of the tail; and by 9 G. II. cap. 33. no *lobster* are to be taken on the coast of Scotland from the first of June to the first of September.

FISHERY, mackerel. The *mackerel* is a salt-water fish, without scales. Its body is round, and fleshy; terminating almost in a point, at each extremity.

Some persons well skilled in the naval architecture, hold it figure the most commodious for swimming of all others, and propose it as a model for the building of ships.

It is ordinarily about a foot long; when in the water, it appears yellow, and when out of it, of a silver white, excepting four streaks, or speckles, of a deep blue, on the back and sides. See *MACQUEL*.

The *mackerel* is a summer fish of passage, found in large shoals, in divers parts of the ocean, north and south; but especially on the French and English coasts.

The fishing is usually in the months of April, May, and June, and even July, according to the place. They enter the English channel in April, and proceed up to the straits of Dover, as the summer advances; so that by June they are on the coasts of Cornwall, Sussex, Normandy, Picardy, &c. where the *fishery* is most considerable. They are an excellent food, fresh; and not to be despised, when well prepared, pickled, and put up in barrels: a method of preserving them chiefly used in Cornwall.

Naturalists have observed, that the water wherein *mackerel* has been boiled, often yields a light, after stirring it a little. See *FIRE*, and *Luminous fish* of the SEA.

The fish is taken two ways; either with a line, or nets: the latter is the more considerable, and is usually performed in the night-time. The rules observed in the fishing for *mackerel* are much the same as those already mentioned in the *fishery* of *herring*.

There are two ways of pickling them: the first is, by opening and gutting them, and filling the belly with salt, crammed in as hard as possible with a stick; which done they range them in rows, or tiers, at the bottom of the vessel, strewing salt between the layers.

In the second way, they put them immediately into tubs full of brine, made of fresh water and salt; and leave them to steep, till they have imbibed salt enough to make them keep; after which they are taken out, and barrelled up, taking care to press them close down.

Mackerel are not cured or exported as merchandise, except a few by the Yarmouth and Lowestoft merchants, but are generally consumed at home, especially in the city of London, and the sea-ports between the Thames and Yarmouth, call, and the Land's end of Cornwall, well.

FISHERY, eel. is principally carried on at Colchester, in Essex; Feverham and Milton, in Kent; the Isle of Wight; the Swales of the Medway; and Tenby, on the coast of Wales. From Feverham, and adjacent parts, the Dutch have sometimes loaded a hundred large hoys with *eels* in

in a weir. They are also taken in great quantities near Portsmouth, and in all the creeks and rivers between Southampton and Chichester; many of which are carried about by sea to London and to Colchester, to be fed in the pots about Wareham, and other places. See OTSTAR.

PIPER, fish. See **PEARL fish.**

PIPER, fish. The *piper* is a small salt-water fish, bigger than the anchovy, but less than the herring, which in other respects it resembles. Its head is yellow, its belly white, and its back sea-green. It eats admirably, fresh, or lightly salted. See **PILCHARD.**

There are certain seasons for fishing the *piper*, which, like the herring and anchovy, is a fish of passage; and its arrival is indicated by similar signs with that of the herrings. They are prepared and sold much as the anchovy is; with this difference, that the head is cut off the latter; but the *piper* were distinguishable from the anchovy, even though its head were off like-wise; the *piper* having a very flat back, and the anchovy a round one.

The chief *piper* fisheries are along the coasts of Dalmatia, to the south of the island of Sicily, on the coasts of Bretagne, from Belle Island is far as Breiz; and along the coasts of Cornwall and Devonshire.

It is a saying of the Cornish men, with regard to the *piper*, that it is the best fish in sea, most in number, and greatest in gain, as they take out of the sea. This observation is amply confirmed by Dr. Borlase's account of this fishery. For besides the great number of persons employed by it, the poor are fed with the oil of the captures, the land with the refuse of the fish and fish, the merchant finds the gains of continuation and commerce, and the fisherman the gains of the fish. The usual produce of the number of hogheads exported each year, for ten years, from 1747 to 1756, inclusive, from the four ports of Fowey, Falmouth, Penzance, and St. Ives, amounted to 29,795 hogheads. Every hoghead for ten years last past, together with the bonus allowed for each hoghead exported, and the oil made out of each, has amounted, one year with another, at an average, to the price of 1*l.* 2*s.* 1*d.* and 3*d.* so that the cash paid for *piper*, exported has, at a medium, annually amounted to the sum of 49,334*l.* 10*s.* The number taken at one shooting out of the net is amazing great. In 1757, there were at one time isolated in St. Ives's bay 7000 hogheads, each hoghead containing 35,000 fish; in all 245,000,000.

That on the coasts of Dalmatia is so plentiful, that it not only furnishes all Greece, but a great part of Italy. That on the coasts of Bretagne employs yearly above three hundred sleepers, and most of the fishermen of the country.

The fish caught on our own coasts, though bigger, are not so much valued, as those on the coasts of France; owing principally to their not being so thoroughly cured. The season is from June to September.

The *piper* naturally follow the light, and will pursue about a boat that bears a light in the night time; which contributes much to the facility of the fishery.

On the coasts of France they make use of the roes of cod-fish, as a bait; which, thrown into the sea, makes them rise from the bottom, and run into the nets, placed for that purpose.

On our coasts, there are persons, called in Cornwall *harris*, posted ashore, who, spying by the colour of the water where the shoals are, make signs to the boats, to get among them, to call their nets.

When taken, the fish are brought to a warehouse on shore, where they are laid up in broad piles, supported by backs and sides.

As they pile them, they salt them with bay-salt; in which they lie soaking twenty or thirty days, and discharge a great quantity of blood, with dirty pickle, and bittern; which last draws much of the oil from the fish, to the great loss of the owners. When taken out of the pile, there remains a quantity of salt, blood, scales, &c. at bottom, which, with fresh salt, serves for another pile.

They now proceed to wash them in sea-water to clear off the dirt and blood; and when dry, they put them up in barrels, and press them hard down to squeeze out the oil, which issues away at a hole in the bottom of the cask, and in this state they are fit for sale, or use.

PINKERY, salmon. The *salmon* is a northern fish, being unknown in the Mediterranean sea, and other warm climates, and, according to some, breeds in the sea; but the opinion of others seems better warranted, that it breeds in the clear stony parts of rivers, remote from their mouths. They commonly season in November, and when they have found a place fit for the purpose the male and female unite in forming a proper receptacle for it in the sand or gravel, about the depth of eighteen inches; in this the female deposits her spawn, and the

male his milt, which they cover carefully, as it is said, with their tails; but after spawning they are observed to have no fun on that part. The spawn lies buried till the spring. The milt and spawn, having performed their office, betake themselves to the sea; and if their return be prevented by storm, or the like, they become fish-lean, and are then called *kipper*, pine away, and die in two years time. If they come in the mean time, the produce is a diminutive *salmon*, called *kipper*, which will never arrive at the natural bulk; it being the sea that makes them grow big, and the rivers fat. The female is distinguished from the male, in that its roe is longer, and more hooked, its scales not so bright, and its body speckled over with dark brown spots, its belly flatter, and its skin not so red; more dry, and less sensitive to the salt. In spawning time, when they repair from the sea up to the rivers, scarce any thing can stop their progress. Many have seen them leap up cascades and precipices, many yards high. See **SALMON.**

When the *salmon* first enter the fresh water, they have a number of insects, the *liver* *salmon* of Linnaeus, adhering to them, especially above the gills, which are signs that the fish is in high season; these die and drop off soon after the *salmon* have left the sea. About the latter end of March, the spawn begins to excrete the young, which gradually increase to the length of four or five inches, and are then termed *smelts* or *imous*; and about the beginning of May the Tweed, &c. is full of them; but they are soon hurried away to the sea. About the middle of June the earliest of the fry begin to drop, and it were into the river again from the sea, being about twelve, fourteen, or sixteen inches, and they gradually increase in number and size till about the end of July; (at Berwick the fish in this stage is called *gillie*) when they again lessen in number, and increase in size, some being six, seven, eight, or nine pounds in weight.

The chief *salmon* fisheries in Europe are along the coasts of England, Scotland, and Ireland. The fishing usually begins about the first of January, and ends by the tail of September. It is performed with nets, in the places where the rivers empty themselves into the sea, and along the sea-coasts thereabout. The fish are seen to crowd thither frequently in shoals from all parts, in search of the fresh water; they also fish for them higher up in the rivers; sometimes with leas, and sometimes with a kind of hooks, or weirs, made for the purpose, with iron gratas therein, so disposed, so that the fish, in going up the river, open them with their head; but are no sooner entered, than the gate caps to. Thus the *salmon* are inclosed as in a reservoir, where it is easy to take them. In some places they fish for *salmon* in the night time, by the light of torches, or kindled *bees*. The fishermen watch when the fish draws towards the light, where it is natural; a great lever, and strikes him with a pest, or hilt. In some parts of Scotland, it is said, they ride a fishing up the rivers, and when they spy them in the shallow parts, shoot them with fire-arms.

Salmon form, in several countries, a great article of commerce, being cured in different ways, by salting, pickling, and drying. There are stationary fisheries in Iceland, Norway, and the Baltic; but those at Coleraine in Ireland, at Berwick in Great Britain, and in some of the rivers of Scotland, are the most considerable. The capture in the Tweed near Berwick, about the month of July, is prodigious; a boat load, and sometimes near two, is taken in a trice; and it is common to take from fifty to a hundred fish at one haul. At this time the coopers in Berwick begin to salt both *salmon* and gillies in pipes, and other large vessels, and then barrel them to send abroad. The *salmon* barrel holds about forty-two gallons, wine measure. Most of the *salmon* taken before April is sent fresh to London; and that which they fail to send is boiled, pickled, and kilted. Fresh *salmon* has also been sent to London in the latter end of September; but then the fish are full of large roes, very thin bellied, and are esteemed neither palatable nor wholesome. In the month of July a tone of fresh *salmon* of eighteen pounds ten ounces and a half, has been sold at Berwick for eight pence; but the more common price is between sixteen pence, and two shillings and sixpence. The season for fishing in the Tweed begins the thirtieth of November, though the fishermen work very little till after Christmas, and ends on Michaelmas day. There are on this river forty-one considerable fisheries, besides others of less value, rented for near 400*l.* per annum.

Scotland possesses also great numbers of fine fisheries on both sides of that kingdom. The *salmon* are cured in the same manner as at Berwick; and a great quantity is sent to London in the spring; but after that time the adventurer begins to barrel and export them to foreign countries; though the demand for them is much abated at

late years. They have also in Scotland a great deal of *salmon*, fished in the common way, which after soaking in brine for a competent time, is well pressed, and then dried in smoke; this is called *kipper*, is chiefly made for home consumption, and is properly cured and prepared, is reckoned very delicious food. The north of Ireland abounds with this fish; the most considerable *fishery* is at Cranna, about a mile and a half from Coleraine, rented, in 1754, for 620*l.* a year. It is situated on the river Ban, where they fish with nets eighteen score yards long, and are continually drawing night and day through the whole season, which lasts about four months; eight hundred and forty fish have been taken at a single draught. There is also a weir on the river, which takes the fish that escape the nets. In 1760, three hundred and twenty tons were taken in the Cranna *fishery*. The *salmon* are cured in this manner: they are first split, and the guts and gills, and many of the bones, are taken out, and then rubbed with fine salt; and after lying in pickle in large tubs for six weeks, are packed up with layers of coarse brown Spanish salt in casks, six of which make a ton. These are exported to Leghorn and Venice, &c. at the price of twelve or thirteen pounds a ton. Pennant's Brit. Zool. vol. iii. p. 284. 294.

The stat. 4. and 5. Anne, cap. 21. was made for the increase and preservation of *salmon* in the rivers in the counties of Southampton and Wilts, requiring that no *salmon* be taken between the first of August, and twelfth of November, or under size, &c. And by 1 Geo. I. cap. 18. *salmon* taken in the rivers Severn, Dee, Wyfe, Were, Ouse, &c. are to be eighteen inches long, at least; or the persons catching them shall forfeit 5*l.* And by 30 Geo. II. cap. 21. no *salmon* is to be caught in the rivers Thames and Melway between the eleventh of November and twenty-fourth of August, or to be of less weight than six pounds.

Salmon is also fished for in rivers, after the manner of trout, with a line and hook. He bites best in the afternoon, about three, in May, June, July, and August; the water being clear, and a little breeze of wind blowing; especially if the wind and stream be contrary ways. The *salmon* is caught like a trout, with worm, fly, and minnow; and especially the garden-worm, if well scoured, and kept twenty days in mofs. The *salmon* never lays long in a place, but is continually shifting to be as near the spring-head as possible, and swimming generally in the deepest and broadest parts of the rivers, near the ground. Put two or three garden-worms well scoured on your hook at once, as if you were baiting for trout; and be sure to give him time to gorge his bait, before you strike. Some use a wire-rope on the top of the rod, through which the line may be let run to any length at pleasure, by a reel near the hand.

FISHERY, *sturgeon*. The *sturgeon* is a large fish, which at its season runs up the rivers, having a sharp-pointed snout, a flat belly, and bluish back. *Sturgeons*, as well as whales, are reckoned among the number of ROYAL FISH. There are *sturgeons* of all sizes; and we even read of some twenty feet long; but those of the middle size are reckoned the best; though some prefer the smaller. See STURGEON.

It is of the roe or eggs of this fish that the CAVIAR, or kavia, so much prized by the Italians, &c. is prepared.

Sturgeons, when fresh, eat deliciously. To make it keep, they salt or pickle it in large pieces, and put them up in cags, from twenty five to fifty pounds.

The greatest *sturgeon fishery* in the world is in the mouth of the Volga, in the Caspian sea; where the Muscovites find employment for a great number of men. We have lately had a considerable supply of *sturgeon* from North America, which rivals that of the Baltic.

They are not caught in nets but in a kind of enclosure, formed by huge fakes, disposed in triangles, representing the letter *Z*, several times repeated. These kinds of *fishery* are open on the side towards the sea, and close on the other; by which means the fish, ascending in the season up the river, embayments itself in these narrow, angular retreats; and, not being able to turn itself, to go back again, on account of its bulk, is easily struck, and killed with a sort of larding-iron. They are also taken, during summer, in the lakes Frischelshaff and Curich-haff, near Pilau, in large nets, made of small cord; the adjacent fakes are formed into districts, and farmed out to companies of fishermen; some of which are rented for six thousand guilders, or near 700*l.* per annum.

The chief object of this *fishery* is the roe or spawn, which is a commodity as much used in Muscovy as butter in Holland; and there are some *sturgeons* that furnish each four hundred pounds thereof. It is only the lesser and younger *sturgeon* that they pickle for eating.

FISHERY, *turbot*. See TURBOT.

FISHERY, *whale*, or Greenland FISHERY. This huge fish,

we have elsewhere observed, is chiefly caught in the North sea. The largest sort are found about Spitzbergen, some of them being there two hundred feet in length. Those on the coasts of America are about ninety, or a hundred; and those on the coasts of Gayenne, and the Mediterranean, are the smallest of all.

The first persons that seem to have been employed in the *whale fishery* were the Norwegians; probably soon after their discovery of Greenland, about the year 852; for we find, that King Alfred received information from Othier, a Norwegian, in 887 or 890, that the Norwegians were employed in this *fishery*. He tells the king, that he sailed along the Norway coast, as far north as the whale-hunters commonly use to travel; but it seems that all knowledge of this painful employ was lost, at least in this country, for almost seven centuries. The Biscayers were also concerned in it, for the sake not only of the oil, but also of the whale-bone, before the English; for, though their north-east discoveries in 1555 had pointed out the way to the *whale fishery* at Spitzbergen, they were so ignorant of the business in 1575, as to be under a necessity of procuring information and assistance from Biscay for this purpose. The first mention that occurs in the English history of whale-fins, or whale-bone is in 1593, when eight hundred fins, part of the cargo of some Biscay ship, that had been wrecked three years before, were brought to England, from the bay of St. Laurence in America by an English ship; previous to which time, the ladies flays, as Mr. Anderson observes, must have been made of split or some other tough and pliant wood; the *whale fishery* being carried on for the sake of the oil long before the discovery of the use of the whale-bone, which was first brought to England, with the blubber or oil, in 1597. The English having been accustomed to the Northern sea, by their repeated trials for a north-west and north-east passage to China, in 1598 commenced their *fishery* for walrus at or near Spitzbergen, where these animals resort in greater numbers than elsewhere. But the first English voyage for the purpose of killing *whales* was undertaken by the Russian company in 1611, who sent two ships thither, with six Biscayers, expert in the business; the ships were lost, though their men and boats, &c. were saved by a ship of Hull, then at Spitzbergen. In 1618, the East-India adventurers joined stock with the Russian company for pursuing the *whale fishery*, and fitted out thirteen ships, but the voyage proved unsuccessful. The manner of managing the whale fishing both by the English and Dutch was then quite different from the present mode; the whales, having never been disturbed, resorted to the bays near the shore, so that their blubber was easily landed at Spitzbergen, where they erected cockleets, i. e. coppers, &c. for boiling their oil; and thence they left standing from year to year, and only brought home the purified oil, and the whale-bone. The English, having been the first in that *fishery*, kept possession of the best bays; the Hollanders, coming later, were obliged to find bays farther to the North; the Danes, who came later into this trade than the Dutch, got in between the English and Dutch; the Hamburgers came after the Danes, and after them came the French, and also the Biscayers, the most ancient whale fishers in Europe, except the Norwegians, and pursued the same method. But, since those times, the whales are less frequent in the bays, and are commonly among the openings of the ice farther from the land; so that the blubber is now cut from the whales, after they are killed, in the manner described in the sequel of this article, and brought home to be boiled and purified, and the whale-fins are also to be cleaned at home. This latter method of fishing, being dangerous to shipping, discouraged our English adventurers who traded in a company; so that they soon after, viz. in 1619, relinquished the *fishery*. Some private adventurers prosecuted the trade with various success in 1621, 1622, and 1623, when they were met by the Dutch, who were then superior in number of ships, and had the prince of Orange's commission; for in 1622, the Dutch, for preventing of disturbance in their *whale fishery*, had erected an exclusive company, who, by their own power, might protect it; however, the *fishery* was laid open, in 1643, to all the inhabitants of the seven provinces. As to the claims which different European nations have alleged in favour of a monopoly of the *whale fishery* at Spitzbergen, it has been urged by the English, that they were the first discoverers, by Sir Hugh Willoughby, in 1555; by the Dutch, who deny his having been so far north as Spitzbergen, and maintain their having first discovered it in 1596; by the Danes, that Spitzbergen is a part of Old Greenland, possessed in early times by them. But all nations have now wisely given up their exclusive pretensions, and that part of the world remains now alike free to all nations

for this fishery. In 1629, king Charles I. confirmed, by his proclamation, the Greenland monopoly solely to the Russia company, who soon relinquished it. In 1672 an attempt was made for reviving this fishery, when an act was passed for the encouragement of it; and this act was continued in 1699, but without any great effect. A corporation was established by act of parliament, in 1699, for carrying on this fishery, called the GREENLAND COMPANY.

In 1725 the English South-sea company received this trade, but, after great losses, were obliged to discontinue it in 1733. At this time a bounty of 200. per ton was granted in parliament to British ships of two hundred tons and upwards, fitted out for the whale fishery, which bounty was not only continued in 1740, but an additional bounty of 100. per ton was granted during the war with Spain, in which we were then engaged; and in 1759, a further bounty or allowance of 200. over and above that of 1733, was granted in all British whale-fishing ships, and extended to ships of the British American colonies; and in 1755 this bounty was extended to ships under two hundred tons burthen; and, as a further encouragement to this fishery, foreign protestants, leaving their years in it, were naturalized on certain conditions. See HICKLEY'S Coll. Voyages, and Anderson's History of Commerce.

But, notwithstanding the great importance and numerous advantages of this trade in England, and the encouragement which the legislature has given to the Dutch have carried it on with much greater success than the English; and it is now extended one of the principal branches of their profitable trade. The chief merchants of the several provinces associate themselves into a body for carrying it on, and send every year a great fleet of vessels to the North seas for that purpose. They attempted to make their first establishments in Greenland; but not succeeding, they have since fixed their views about the western coast of Spitzbergen, from the latitude of 70 deg. 40 min. to 80 deg. and from east to west about eighty-one leagues.

To give some idea of the manner and importance of this trade, we shall here follow the discipline of a long time observed in the whale fishery; the method of fishing; the cargo and equipage of a vessel; and the produce thereof.

The discipline is regulated by a standing regulation, consisting of twelve articles; the principal whereof are:

That in case a fishing-vessel be shipwrecked, and the captain and crew saved, the next vessel they meet shall take them in; and the second vessel take half of them from the first; but that no vessel shall be obliged to take any of the loading of a vessel shipwrecked; that as to the effects of a shipwrecked vessel, which are absolutely relinquished, and which another captain shall find, and take up, upon his arrival in Holland, he shall account for one half of them to the proprietors of the shipwrecked vessel, clear of all expenses; that, if the crew desire a shipwrecked vessel, they shall have no claim to any of the effects saved, but the whole shall go to the proprietors; but if they be present when the effects are saved, and assist therein, they shall have one fourth thereof; that if a person kill a fish on the ice, it shall be reputed his own, so long as he leaves any person with it; but the minute he leaves it, it becomes the due of the first captain this comes that way; but that, if a fish be tied to an anchor, or a rope fastened to the shore, it shall remain in its first possession, though he leave it alone; that if any person be wounded or injured in the service, the commissioners of the fishery undertake to procure him a reasonable satisfaction; in which the whole fleet shall contribute.

Besides this general regulation, to the observance of which all the captains, pilots, and masters of vessels, are obliged to swear, before they put to sea, there is also a particular one for each ship's crew, which they are all sworn to execute in presence of one of the commissioners, who goes aboard every ship, to receive the oath. This regulation is a kind of charter-party, importing, that they will attend prayers morning and evening, on pain of an amercement, at the discretion of the captain; that they will not get drunk, nor serve their knives, on forfeiture of half their wages; nor fight, on forfeiture of the whole; that no one shall fly weapons on the board or in the face of the fishing, nor buy or sell, on these conditions, in case we take one for more fish, on penalty of twenty-five shillings; that they will be contented with the provisions allowed them; and that they will nevertheless live, mangle, or mangle, by night or day, without the captain's leave, on the like penalty.

After the reading of this regulation, the crew are all called, to receive the customary gratuity before their setting out, with an allowance of another sum at their return, in proportion to the success of the fishing.

The captain, on this occasion, receives from a hundred to a hundred and fifty shillings; the pilot from forty to fifty; each harpooner from forty to fifty shillings; the other officers from twenty-six to thirty-six shillings; the older sailors twenty; and the younger twelve.

The fleet, which consists mostly of Dutch, from two to three hundred tons, and from thirty-six men to forty-two, usually sets sail about the beginning of April, and takes its course by the lies of Iceland, from 60 to 61 degrees of latitude; after which, leaving them to the west, it fleets northward, through 73, 74, and 75 deg. of latitude, where they begin to find the ice.

It is among these huge heaps of ice, wherewith the whole quarter is filled, that they first begin to try for whales; and there most of the vessels fix their shore for the fishing. But as the fish are larger and finer the farther north they go, some captains will venture as far as 80 or 82 deg. of north lat. Each vessel of three hundred tons has six hallooos; and each halloo has six harpooners, with five seamen to row it. To every halloo there are seven lines, of three inches circumference; five of them in the hind part of the vessel, and two before. The hind line together make six hundred fathoms, and, with the addition of the other two, eight hundred and eighty. If the whale five degrees, or two further under the ice than this first, the line must be cut, lest the halloo be drawn after it.

In the English whale fishery every ship has six or seven boats, each of which has one harpooner, one boat-sweeper, one manager of the line, and four seamen to row it. In each boat there are two or three harpooners, several lines, and six lines fastened together, each line being a hundred and twenty fathoms long. To each harpooning iron is fastened a strong stick, about six feet long, and a flimsy line, about six fathoms long, called the fore-gauge, which is fastened to the lines in the boat. When more line is wanted, the lines of a second boat are fastened to those of the first.

The instrument, wherewith the whale is struck, is a stick, six or seven, or seven, five or six feet long, pointed with steel, in a triangular shape, like the barb of an arrow.

The harpooner, upon sight of the fish, from one end of the halloo where he is placed, flings the harpoon from with all his might against its back; and, if he be so happy as to make it penetrate the skin and fat into the flesh, he has got a strong fastener to the harpoon-iron at the end whereof is a dry gourd, with a swimming on the water, discover whereabout the whale is; for the minute he is struck, he plunges to the bottom, commonly swimming against the wind.

If the whale return to breathe in the air, the harpooner takes occasion to give him a fresh wound, till, landing by the loss of blood, the whale have an opportunity of approaching him, and thrusting a long barbed lance under his gills into his throat, and through the intestines, from which he dies; and when the carcass begins to float, they cut holes in the skin and tail; and, tying a rope in these holes, they tow him to the vessel, where he is fastened along the forward side of the ship, having upon his back a small level with the sea. They then begin to take the blubber or fat, and the fish, as they are called, or whale-bone.

In order to this, several men stand upon the fish, with a kind of iron calkons, or tools, to prevent their slipping; and cut off the tail, which is hoisted upon deck, and then cut out square pieces of blubber, weighing two or three thousand pounds, which are hoisted on board with the capstan, where each piece is again cut into smaller pieces, each of two or three hundred pounds weight; and these are thrown into the hold, and left to drain for three or four days. When all the blubber is cut from the body of the fish, it is turned on one side, by means of a piece of blubber, left in the middle, called the *lard* or turning-piece; and then they cut out this side in large pieces, called *blubber*, as before, and fling the whale-bones with the gums, which are preferred entire, and hoisted on deck, where the blades are cut out separated, and left all they have time to clean and scrape them. The fish is next turned on his back, and the blubber cut out from the back and crown bone; and last of all they cut the blubber from the other side, as before. They then cut out the two large jaw-bones, inserted in the joints, which are hoisted on deck, cleaned, and stowed in the bins, and tails are placed under them to receive the oil, which they discharge; the oil belongs to the captain, and likewise the tail and fins. The carcass is left to rot, and supplies food for Greenland fish, called mallow-meat, &c. In three or four days, they lay the pieces of blubber out of the hold, chop them, and put small pieces through the bung holes into their casks. A whale, the longest blade of whose mouth is nine or

ten feet, generally fifty thirty boats with blubber; but one of the largest will fill seventy boats and more. A good large whale is valued at about 10000 sterling. A full ship of three hundred ton is worth, clear of all expense, at least 50000. There is a premium allowed to every person in the ship for every whale; the captain has three guineas; the mate, one; each harpooner, one; the foreman, one; carpenter, one; cook and boat-steerer, half a guinea each; a common man, a crown; and each boy, half a crown. The captain and harpooners have no wages; but the captain is allowed twenty-five pounds, and the harpooners, nine guineas each. In a successful voyage they have six shillings for every ton of oil bottled in Greenland-dock; but the rest of the ship's company have monthly wages besides the fish-money, but no oil-money.

Nothing now remains, but to sail homewards, where the fat is to be boiled, and melted down into train-oil.

The *whale-fishery* of the Caroline islands is more easy and agreeable than that of all other places, and, beside the great profit, affords a pleasant spectacle to multitudes of people on the shores.

There are ten or twelve of these fisheries disposed in form of a circle, so that they make a sort of port, in which the sea is perpetually calm and pleasant.

When a whale appears in this gulf, the people all get into their canoes, and towing towards the sea, keep between the creature and its retreat, and drive him forwards towards the ships at the bottom of the port. They drive him in this manner before them into the shallows, where they plunge into the water, themselves, and some get ropes and chains about him, while others dart him with their spears. Their agility and address is wonderful in this, the creature can never get away when they have once got him fastened, but is soon killed, and got to the shore.

FISHERY, *principle of the sea*. To state the produce, we make choice of the *fishery* of 1697, as being one of the greatest, and most fortunate, that ever was known; to which we shall add that of the year 1725.

In the year 1697, there were a hundred and eighty-nine vessels of divers nations; whereof a hundred and twenty-one were Dutch; forty-seven Hamburgers; two Swedes; four Danes; twelve of Bremen; two of Embden; and one of Lubbeck; who caught in all 10668 fish.

In the year 1725, there were two hundred and twenty-six vessels; whereof one hundred and forty-four were Dutch, twelve English, forty-three Hamburgers, twenty-three of Bremen, two of Berghen, two of Flensburgh. Their captures were 349 fish.

The Dutch captures in 1697, produced 41344 punch-coats	
The Hamburgers —————	16414 of blubber
The Swedes —————	540
The Danes —————	1730
The Brementers —————	3790
The Embdeners —————	68

The English captures in 1725, produced 1000 punch-coats of blubber, and 20 tons of whale-bone.

Now, estimating the punch-coat of blubber at thirty florins, Dutch, or 2l. 12s. English, the current price in the year 1697, the total produce of the year's *fishery* amounts to 1273031l. 10s. sterling. As to fins, or *whale-bone*, setting them at two thousand weight per cask, and 20 hundred weight at 2l. 4s. they will yield 165312l. sterling, added to the former sum, amounts to 3450943l. 10s.

Mr Anderson in his *History of Commerce*, vol. II. p. 350. observes, from an account of the Dutch *whale-fishery* for forty six years, ending anno 1721, that in this time they had employed 5886 ships, and caught 3507 whales, which valued one with another at 5000, give an amount for the whole value of above 16 millions sterling, gained out of the sea solely by the labour of people, deducting the expense of the wear and tear of shipping, the casks and the provisions. The *whale-fishery* begins in May, and continues through the months of June, and July; but whether the ships have had good or bad success, they must come away and get clear of the ice by the end of August; so that in the month of September at farthest they may be expected at home; but the more fortunate ships may return in June or July.

FISHES, aboard a ship, are pieces of timber, convex on one side, and concave on the other, used to strengthen the masts and yards, when they begin to fall, through an extraordinary weight of sail, or if it be dangerous to set, or if tempestuous weather. They both make the *fish* on which iron fishes, and also work them, as they call it, that is wind ropes hard about them. There is also a tackle called the *fish*, which hangs at the end of a derrick by the strap of the block, in which is the runner of the *fish-haul*, by which means the fluke of the anchor is

hauled up, to the ship's bow or sternward. See **BLUCKS**. Perhaps this tackle was called a *fish*, from that which the ancients called a *fish*, which was a pointed and sally heavy piece of iron, which they used to heave up by a tackle to a good height, and then, when they came near enough to the enemies ship, let it fall at once, to break or pierce a hole through the bottom of the enemies vessel, and sink her.

FISH-GEAR, an instrument used to strike *fish* at sea, particularly dolphins. It consists of a staff, three or four barbed prongs, and a line fastened to the end, on which, the prongs are fixed to the other end is fitted a piece of lead, which serves to give additional force to the stroke, when the weapon flies, and to turn the points upwards after the *fish* is penetrated.

FISH-GARTER, according to Skinner, signifies an engine to take *fish*; but it should rather seem to denote the dam or weir in a river, where these engines are laid and used.

FISH-GLUE. See **LEITHYCOLLA** and **GLUE**.

FISHING, the act or art of catching *fish*.

Right of *fishery* and the property of *fish* belong in the lord of the manor, when he hath the soil on both sides of a river; but where a river cuts and flows in an arm of the sea, they are common to all, and he who claims a privilege to himself must prove it. In the Severn, the soil belongs to the owners of the land on each side, and the soil of the river Thames is in the king, &c. but the *fishery* is common to all. There are several statutes for preventing the destruction of the fry of *fish*; and persons along nets for that purpose, or taking salmon or trout out of season, or any *fish* under certain lengths, are liable to forfeit 20s. and jail for a year, and lords of seigns have power to put the acts in force. See **ELIS.** cap. 12. 3 Jac. 1. cap. 17. 2 Geo. II. cap. 21. See **SCOTCH FISHERY** and **Stocking of Fish**.

Fishing is distinguished with regard to its instrument into that performed with the net for *fish* that go in shoals; and that with the hook, for solitary *fish*; which latter is properly called *angling*.

Fishing, again, is distinguished with regard to its object into that performed in salt water and that in fresh. The first practised for whales, herring, cod, salmon, pearls, muskell, and other sea-fish. The latter practised for pike, trout, carp, tench, perch, dace, eels, &c.

The instruments principally used in angling of *fish* with the hook, are the rod, line, hook, and fly. The points on which the art of *fish* chiefly turns are the proper season, place, bait, and manner of application. What relates to each thereof we shall here give the reader in the several kinds of *fish* chiefly practised among us.

In March, April, and September, the warmest days are the best for *fish*; and the bait must be deep for the *fish* in these cool months be near the bottom. In July, when it is always observed, that the *fish* will rise before a small shower of rain, that has fall but down the river, upon the water without storming in it. March, April, May, and June, are the best months for *fish*; and the best hours are about nine in the morning, and three or four in the afternoon in a still warm evening; they will bite as long as the day-light lasts, at those seasons when the gulls are seen most plentifully about in the air.

In the extremity of heat, when the earth is parched with drought, there is but little sport to be expected in *fish* in any water. In cold weather, when there is a white hoary frost in the morning, the *fish* will not bite kindly all day, except in the evening, if that should prove serene and warm.

Too much wind is never convenient for *fish*, though a little is rather advantageous than otherwise. It is bad *fish* about deep-thundering time, in waters where the deep are washed; for the *fish* glut themselves in such a manner with what is washed from these creatures, that they will not take any bait till that season is over.

North and east winds are enemies to *fish*; and it is not right to fish long after the time of the *fish* thawing, for they are then sick, and have no great appetite, so that they do not bite readily. All *fish* have a natural fore-knowledge of a shower of rain, and when clouds are coming on, that will fall in rain, they will not bite; the expert angler, who is used to this, often catches being sent to the *fish* by it.

The fisherman's or underground *fish* of the Lake Ristchymund, has been much distressed by those who have walled the Zichmunder See, of which is a part, but of the whole it amounts to no more than this. The waters of this lake emptying themselves through subterranean passages into another lake below, the whole body of the water, with the *fish* in it, is first received into a large opening, which conveys it into a sort of reservoir

been bafon, in the bottom of which there are many holes, and through these the water is let out, but the fish left behind. The people of the place who know this, descend through the large hole into this subterraneous basin with torches in their hands, and as the waters run off, they seize upon the fish wherever they can catch them. This sort of fishing is attended with one inconvenience; for the people being obliged to stand up to the middle, more or less, in the water, the horse-leeches, which are extremely plentiful there, seize upon their legs and other parts, and are only to be got off by some person's making water upon the part; the heat and nauseous rille of the urine always making them let go their hold. Phil. Trans. N^o 91.

FISHING, *salts-head*. See BAIT.

The season for taking *salts-head* is only from the first of August to the first of October. 30 Geo. II. cap. 21.

FISHING, *barbel*. See BARBUS.

No *barbel* is to be taken in the Thames or Medway under twelve inches in size, from the eye to the end of the tail, and only between the twenty-fourth of August and the twenty-first of March. 30 Geo. II. cap. 21.

FISHING, *carp*. The *carp* is generally held the queen of fresh-water fish. It is exceeding fat, and of all others, the eat only excepted, lives longest out of water. Mr. Ray assures us, that in Holland they have a speedy way of fattening them, by hanging them up in a net in a cellar, and feeding them with white bread and milk. See the method described under *CARP*. They breed several times in the year, for which reason we seldom meet with male or female without either milt or spawn. Their natural place is some still water; in running waters they rarely, if ever, breed. To make them fat and large, it is a good way, when the pond is low, in April, to rake all the edges thereof with an iron rake, and sow hay-seeds thereon. By autumn there will be a crop of grass, which, coming to be overgrown as the pond rises, will be a fine feeding-place for them.

Great patience is requisite in angling for *carp*, on account of their incredible policy. They always choose to lie in the deepest places; they seldom bite in cold weather; and in hot, a man cannot be too early or too late for them. When they do bite, there is no fear of the hold. The tackle must be very strong, and it will be proper to bait the place beforehand where it is to be fished for, with a coarse paste. It may be also proper to bring the *carp* to the place intended for angling, by throwing in crowding and blood, or bran and blood mixed together, or some chicken guts cut small. The baits are the red-worm, in March; the catfish, in June; and the grass-hopper, in July, August, and September. Proper pails may also be prepared for them, as honey and sugar, wrought together with flour, and thrown in pieces into the water some hours before they begin to angle. Hens and white crumbs of bread mixed together, also make a good pail. The following pail is much recommended: take common wheat flour and meal, or any other young meat, of each equal quantities; beat them together in a mortar till the meal is thoroughly dissolved or broke to pieces; then add about half the quantity of honey; beat it well together again, and add more flour till the whole is of a proper consistence. This has the advantage of a pail, and of an animal bait, and hangs well upon the hook, so that it seldom fails of success.

The best season for catching such as are intended for sale is in autumn. See *CARP*.

FISHING, *chub*. The *chub* or *shub* is a fresh-water fish with a large head. It spawns in March, and is very strong, though insipid, yielding in a very little time after it is struck; and the larger it is the quicker. His bait is any kind of worm or fly, particularly the large yellow moth; also grains, &c. the pith in the bone of an ox's back, &c. He affects a large bait and a variety of them at the same hook. Early in the morning angle for him with snails; but, in the heat of the day, choose some other bait, and in the afternoon, fish for him at ground or fly. See *CYPRIN*.

No *chub* is to be taken under nine inches from the eye to the end of the tail, and only between August 24th and March 21, in the river Thames and waters of Medway. 30 Geo. II. cap. 21.

FISHING, *dace* or *dore*. See DACE.

No *dace* are to be taken in the Thames or Medway under six inches from the eye to the end of the tail in size, and only between August 24th and March 21. 30 Geo. II. cap. 21.

FISHING, *el*. See EL.

The *el* may be caught with divers baits, particularly powdered beef, garden-worms or tobs, minnows, hens' guts, fish, partridge, &c. But as they hide themselves in winter in the mud, without stirring out for six months and in the summer, they take no delight to be abroad in

the day, the most proper time to take them is in the night, by fastening a line to the bank side with a hook to the water, or a line may be thrown at large, with a good store of hooks baited, and plumbd, with a float, to discover where the line lies in the morning. A small roach does well here for a bait, the hook being laid in his mouth. For other methods of catching *el*, see *EL*.

NO LEAP, or rods for *el* are to be laid in the Thames and Medway but from April 21 to October 30; but they may be hooked for all the year. 30 Geo. II. cap. 21.

FISHING, *flounder*. The *flounder* is a flat fish or river fish, caught in April, May, June, and July, in any time of the day, in a swift stream, and sometimes also in a still deep. The best bait is red worms, wafers, and gentles. *Flounders* may be taken in the rivers Thames and Medway at any time of the year; but their size must not be less than six inches from the eye to the end of the tail. 30 Geo. II. cap. 21.

FISHING, *gudgeon*. The *gudgeon* is a small fish of a very delicious taste. It spawns three or four times in the summer-season, and feeds in streams and on gravel, lighting all kinds of flies; but is easily taken with a small red worm, fishing near the ground; and being a leather-mouthed fish, will not easily get off the hook when struck. The *gudgeon* may either be fished with a float, the hook being on the ground, or by hand, with a running line on the ground, without cork or float. He will bite well at wafers, gentles, and caddisworms; and one may even fish for him with two or three hooks at the same time, which makes good sport. When you angle for *gudgeons*, stir up the sand or gravel with a long pole, which will make them gather to the place and bite the faster.

The season for *gudgeon* fishing in the Thames and Medway is from August 24th to March 21st. 30 Geo. II. cap. 21.

FISHING, *perch*, or *perch*. The *perch* or *perch* is hook-baited, not unlike a hog, armed with stiff prickles, and his scales with dry thick scales: he is voracious, and will venture on his own kind even with greater courage than the pike. He seldom grows much above a foot long. He spawns in February or March, and bites best when the spring is far spent. The proper baits are the bradling, minnow, and small frog; as also the lob-worm, bob, oak-worm, gentles, wafers, and caddis. The minnow yields the best sport, which is to be alive, and struck on the hook through the upper-lip, or back-in, and kept swimming about mid water. If the frog be used, he is to be fastened to the hook by the skin of his leg. When the fish bites, as he is none of the leather-mouthed kind, he must have time to pouch his bait. The best place to fish for him is in the turning of the water-edy in a good gravel bottom.

No *perch* is to be taken in the Thames or Medway under six inches from the eye to the end of the tail, and only between August 24th and March 21st. 30 Geo. II. cap. 21.

FISHING, *pike*. The pike is reputed the tyrant of the fresh waters. By the common consent of naturalists, he is the longest-lived of all fishes. The larger he is found, the coarser is his flesh; and so *vice versa*. This fish never swims in shoals, but always single, being very rapacious, and preying even on his own kind. The pike spawns in February and March. The best sort is in rivers; the worst in meres and ponds. His ordinary food is frogs, and what fish he can lay hold on.

There are two ways of fishing for the pike by the ledger-bait and the walking-bait. 1. The ledger-bait is thus fixed in one certain place, and which the angler may leave behind him. Of this kind the bait is some living bait, as a dace, roach, gudgeon, or a living frog. To apply it, if a fish, stick the hook through his upper-lip; then fastening it to a strong line, twelve or fourteen yards long, tie the other end of the line to some stake in the ground, or bough of a tree, near the pike's usual haunt, letting the line pass over the fork of a stick placed for the purpose, suspending the hook, and about a yard of line in the water, but so as that when the pike bites the fork may give way, and let him have line enough to go to his hold and paunch. If the bait be a frog, the arming wire is to be put in at his mouth and out at his vent, and one of his legs to be stitched or tied over the upper joint of the wire. 2. The walking-bait is that which the fisher casts in, and conducts with a rod, &c. This is performed by a rod, with a watch for winding it up. As the top of the line is to be placed at a ring for the line to be run through. The line, for two yards and a quarter, tie the hook, to be of silk double, and armed with wire the length of seven inches. On the shaft of the hook is to be fastened a smooth piece of lead, so as to sink the fish bait, which is to be a gudgeon, with its head downwards. Thus disposed, the bait is to be cast up and down, and

If you feed the fish at the hook, give him length enough to draw away with the bait, and paunch it, then finish him with a smart jerk. To fish with a dead bait, use a yellow frog, dace, or roach, anointed in gum of fish dissolved in oil of spike, and cast it where the fish is frequent. After it has lain a little while at the bottom, draw it to the top, and so up the stream, and you will quickly perceive a pike in earnest pursuit thereof. This fish bites best about three in the afternoon in clear water, with a gentle gale, from the middle of summer to the end of autumn, but in winter, all day long; and in the spring he bites best early in the morning, and late at night. Another method of *fishing for pike*, see under Huxing.

No *pike* or *jail* is to be taken in the Thames or Medway under twelve inches from the eye to the end of the tail, and only between August 24th and March 21st. 30 Geo. II. cap. 21.

FISHING, roach. The roach, or racket, is no delicate fish. Those in rivers are more valued than those in ponds, though the latter are much the larger. They spawn about the middle of May.

To angle for this fish in April, catch ee worms are preferable, as are small white fish or flies in summer. The bait is always to be under water, for this fish will not bite at top. Others use May-fly in that fashion with good success. In autumn, a pike must be used, made of the crumb of white bread, moulded with a little water, is bound with the hands into a tough pike, and coloured, not very deep, with red lead. In winter, gentles are the best bait. Spotted min, the young brood of walleye, and bass-bait in blood, and the alkali blood of sheep and deer, are all ways in this sort of *hunting*.

In the original method of London they have a peculiar method of *lifting for reach*; they take a strong cord, at the end of which is fastened a three-pound weight; and a foot above the lead a packthread of twelve feet is made fast to the cord; and to the packthread, at proper distances, they add twelve strong links of hair with reach-hooks at them, baited with a white foal or periwinkle. Then holding the cord in their hands, the bringer of the fish draws the packthread, and this the cord, which gives them more strength. By this means they four times draw away half a dozen, and very commonly two or three at a draught. By St. Geo. H. cap. 27, *no reach* is to be taken in the Thames or Medway under six inches from the eye to the end of the tail, and only between Aug. 24th and March 21.

FISHING, *salt*.—See SMELT.

ly 36 Geo. II. cap. 21. no *fruit* is to be taken in the Thames or Medway less than five inches from the eye to the end of the tail, or at any time, except from January 25th to June 18; and those that are caught in other waters must be of the above size. 33 Geo. II.

FISHING, *fish*. See *SOAL*.

FISHING, tooth. The tooth is a fine fresh-water fish, having very small scales, but large, smooth fins, with a circle about the eyes, and a little barb hanging at each corner of the mouth. It takes more delight among weeds in ponds than in clear rivers, and coverts to food in foul water. His time is said to have a healing quality for wounded fish; upon which he is commonly called the *fisher physician*. When the carp, pike, &c. are hurt, it is said they find relief by rubbing themselves against the tooth.

The season for catching this fish is in June, July, and August very early and late, or even all night, in the Mill part of river. His bait is a large red worm, at which he takes very eagerly, especially if first dipped in tar. He also delights in all sorts of pastes, made up of Brong-tented oil, or with tar; or a pail of brown bread and honey; nor does he refuse the ead-worm, lob-worm, flax-worm, green gentles, cod-bait, or soft boiled bread-again.

When a number of *ambs* are to be taken out of a muddy pond, the method is to take a large calico-net, wet leaders, and with the mothers from the crown to the tail yard and a half, not too small, for them; if the pond is deep, the fish will strike away before the net gets to the bottom. The place where the net is to be thrown into must be cleared of weeds, etc., with a rake. A bait is next to be prepared for drawing the fish together; for this purpose, put a quarter of a peck of wheat into three quarts of water, fend it to an oven, and let it be well soaked; then add to it five pints of blood, and as much bran as is necessary to give it the confidence of pail; mix with it some clay, and add a quart of lob-worms chopped to pieces. Let the whole be wrought up into a fish pail, and rolled into balls of the size of a hen's egg, and throw these into the pond in the place where the net is to be cast. Let these, and some grains, be occasionally thrown in, and the place be thus baited for several days.

Vol. II. N^o 132.

When the fish may be supposed to be well acquainted with the place, let a good baiting be given in the morning and at noon, the baiting for the calling being carefully thrown in. When the fish are taken, the bait should be to be flung with a long pole, with a hook at the end; the net is to be half an hour, and the mud to be thus stirred all the time; by this means the *cond* will be raised, and will be taken by pulling out the net; but if the net were to be thrown in and taken out in the common way, there would hardly be one fish taken; for the custom of both *h* and carp, when they are frightened, is to plunge their heads up to the eyes in the mud, and thus placed with their tails erect, the net must straw over them, without the possibility of entangling them.

ASTURUS, trutt. The trout is a delicious fresh-water fish, speckled with red and yellow, coming in and going out of season with the buck, and spawning in the cold months of October and November, whereas all the other species spawn in hot summer weather. There are several kinds of this fish; all valuable, but the best are the red and yellow *trutt*; and of these the female, distinguished by a less head and deeper body, is preferred. They are known to be in season by the bright colour of their parr, and by their large and thick back, which all may serve also as a rule for other fish. Through the whole winter they are sick, lean, and unwholesome, and frequently loathsome. As the spring comes on, deserting the still deep waters, they repair to the gravelly ground, against which they continue to rub till they get rid of their lice, which are a kind of worms with large heads. From that time they delight to be in the sharp streams, and such as are swift, where they lie in wait for minnows and May-flies. At the latter end of May they are in their prime.

The usual bait wherewith the trout is caught are the worms, minnow, and fly, either natural or artificial. The proper worms are the brandling, lob-worm, four-leaved worm, which has a black round the back, a red head, and a broad tail, earth-worm, dung-worm, and maggot or gentle, especially the three first; the brandling is commonly found in an old dunghill, or under cow-dung or else among tanners' bark; the others are found in the earth, and under large stones and flumps of trees; but whatever worms are used they are the better for keeping, which is to be done in an earthen pot, with moss, frequently changed. To take the trout with a ground-bait, the angler should have a light, taper rod, with a tender hazel point, and may angle with a single hair of three links, the one tied to the other, for the bottom of the line, and a line of three-haired links for the upper part; with this sort of tackle, if the sportsman has room enough, he will take the largest trout in any river. The angler must always keep out of sight, and the point of the rod must be down the stream. The season for fishing for the trout with the ground-bait begins in March, and the mornings and evenings are the best time of the days but in cloudy weather the sport may be followed all day long. There must be a plummet at ten inches from the hook, which the angler must feel, always touching the ground; and this must be heavier as the stream is swift. The minnow, worm, chafe, the whiff, and the tip of muddling fish dip the tail through the mouth, and the point and beard out at the tail, and it may be almost straight on the hook. Then try against the stream, whether it will turn. The tackle in this case may be stronger, for the trout will seize this bait as soon as it comes in sight; the upper part of the line may be of three fillets and three hairs, and the lower of two of each, and the hook may be moderately large. In defect of a minnow, a small loach, or a little loach, may serve the turn; or for want of either, an artificial one may be made of cloth by the life, which is found every where as good a bait as the natural one.

The most agreeable manner of *fishing* for trout is with the fly; the rod in this case must be light and pliable, and the line long and fine; if one bait be strong enough, as it may be made by proper skill in the angler, there will be more fish caught than when a thicker line is used; and the fly-fisher should have the wind in his back, and the sun before him. See ANGLING.

By 1 Eliz. cap. 21. no *trout* is to be taken under eight inches in length; and by stat. 24 Anne, cap. 21. *Sal-trout* is not to be taken in particular rivers, creeks, or arms of the sea between June 30th, and Nov. 11th. By 36 Geo. II. cap. 21. no *trout* is to be taken in the Thames or Medway between November 11th and August 21st, or to be of less weight than one pound.

FRONTING-H, a bait used in angling for divers kinds of fish.

The *fly* is either *natural* or *artificial*.
Natural flies are innumerable: the more useful on this ac-
 count are the *dam-fly*, the *stone* or *Mosquito*, the *red-fly*,
 the *may-fly*, the *twing-fly*, the *vine-fly*, the *hairy-fly*, the
beetle and *black-fly*, the *flag-fly*, also *carapillars*,
 &c.

canter-fly, *hour-fly*, &c. all which appear sooner or later, according to the forwardness or backwardness of the spring. To know the particular fly the fish most covets, when you come in the morning to the river side, beat the bushes with your rod, and take up what variety you can of all sorts of flies; try them all, and you will quickly know which are in most esteem: not but that fish will sometimes change their fly; but it is only when they have sometimes platted themselves therewith.

There are two ways to fish with *natural flies*, either on the surface of the water, or a little underneath it. In angling for chub, perch, or dace, move not your natural fly swiftly, when you see the fish make at it; but rather let it glide freely towards him with the stream; but if it be in a still and slow water, draw the fly slowly sideways by him, which will make him eagerly pursue it.

The *artificial fly* is most successfully used in blustering weather, when the waters are so troubled by the winds that the natural fly cannot be seen, nor rest upon them. Of this *artificial fly* there are reckoned ten principal sorts.

1. The *dun-fly*, in March, made of dun-wool, and the feathers of a partridge-wing.
2. The *dun-fly*, made of black wool, and the feathers of a black drake; the body made of the first, and the wings of the latter.
3. The *blow-fly*, in April, the body made of black wool, dyed yellow under the wings and tail.
4. The *ruddy-fly*, in the beginning of May, the body made of red wool, and bound about with black silk, with the feathers of a black capon, which hang dangling on his sides next his tail.
5. The *yellow or green fly*, in June, the body made of black wool, with a yellow list on either side, and the wings taken off the wings of a buzzard, bound with black broken hemp.
6. The *may-fly*, the body made of dunish wool, and the wings with the blackish mail of a drake.
7. The *may-fly*, till the middle of June; the body made of tawny wool, the wings made contrary one against the other, of the whitish mail of a white drake.
8. The *may-fly*, in July, the body made of black wool, call about with yellow silk, and the wings of drake's feathers.
9. The *may-fly*, in the middle of July; the body made of greenish wool, call about with the feathers of a peacock's tail, and the wings made of buzzard's wings.
10. The *may-fly*, in August; the body made of black wool, call about with black silk, his wings of the mail of a black drake, with a black head.

The best rules for angling *fly-fishing* are,
1. To fish in a river somewhat disturbed with rain, or in a cloudy day, when the waters are moved by a gentle breeze, the fourth wind is best, and if the wind blow high, yet not so hot that you may conveniently guide your tackle, the fish will rise in plain deeps; but if the wind be small, the best angling is in swift streams.

2. Keep as far from the water-side as may be; fish down the stream, with the fan in your face, and touch not the water with your line.

3. Angle always in clear rivers with a small fly and slender wings, but in muddy places use larger.

4. When after rain the water becomes brownish, use an *orange fly*; in a clear day, a light-coloured fly; a dark fly for dark waters, &c.

5. Let the line be twice as long as the rod, unless the river be encumbered with trees.

6. For every sort of fly have several of the same, differing in colour, to suit with the different complexions of several waters and weathers.

7. Have a nimble eye and active hand, to strike presently with the rising of the fish, or else he will be apt to throw out the hook.

8. Let the fly fall first into the water, and not the line, which will scare the fish.

9. In slow rivers or still places, cast the fly cross over the river, and let it sink a little in the water, and draw it gently back with the current.

Salmon should be made with their wings standing one behind the other, whether two or four. That fish delights in the gaudiest colours that can be; chiefly in the wings, which must be long, as well as the tail.

FISHING-HOOKS are little appendages to the line, serving to keep the hook and bait suspended at the proper depth, to discover when the fish has hold of them, &c.

Of these there are divers kinds, some made of Moscow duck quills, which are the best for slow waters; but for strong streams, found cork, without saws or holes, bored through with a hot iron, into which is put a quill of a fit proportion, is preferable; pare the cork to a pyramidal form, and grind it smooth.

FISHING-LEAD, a little engine of steel-wire, of a proper form to catch and retain fish.

The *fish-hook*, in general, ought to be long in the flank, somewhat thick in the circumference, the point

even and straight: let the bending be in the flank. For setting the hook on, use strong, but small silk, laying the hair on the inside of your hook; for if it be on the outside, the silk will fret and cut it asunder.

There are several sizes of these *fish-hooks*, some big, some little; and of these some have peculiar names, as 1. *Singled-hook*. 2. *Double-hook*, which have two bendings, one contrary to the other. 3. *Sawyers* or *gorges*, which are hooks to whip the artificial fly upon, or to bait with the natural fly. 4. *Springers* or *spring-baits*, a kind of double hooks, with a spring which flies open, being struck into any fish, and so keeps its mouth open.

FISHING-ROD. See *Angling-Line*.

FISHING-ROD. See *Net*.

FISHING-ROD, a long slender rod or wand, to which the line is fastened for angling.

Of these there are several sorts, as,

1. A *trailer* or *trailing-rod*, which has a ring at the end of the rod for a line to go through, when it runs off a reel.
2. A *whipper* or *whipping-rod*, a top-rod that is weak in the middle, and top-heavy, but all slender and fine.
3. A *depper*, which is a strong rod, and very light.
4. A *juniper* or *snipe-rod*, that is, a strong pole, peculiarly used for the pike.
5. A *stream-rod*, being the same as the depper, but somewhat more pliable.
6. A *feigling* or *peking-rod*, a forked stick, having a short, strong line, with a needle, baited with a lob-worm; this is only for eels in their holes.

Fishing-rods are made of different materials and strength, according to the purposes for which they are used: in *fishing* with more than one bait, and with a silk-worm gut, red deal is reckoned the best, with hickory top, and the length of the whole rod should be about four yards; but for a small fly and single bait, the length of three yards will be sufficient, with the top of yellowish hickory, and about nine inches of whalebone, near as long as the stock, which should be of white deal. The stocks, or butts of rods, are generally of ground hazel, ash, or willow, about two or three feet long; and every joint should gradually taper to the top. Hazle tops are preferred, though some use the bamboo cane, and say it exceeds the best hazel. For ground angling, especially in muddy waters, the cane or reed is preferred for a stock; with a hazel-top, consisting of one, two, or three pieces, and a small piece of round, smooth, taper whalebone, which is whipped to the hazel with strong silk, rubbed with shoe-maker's wax; the whole length of the rod being five yards, or five and a half yards. The best method of piecing hazel and bone, is first to whip the end of the hazel with thread, and to bore it with a square piece of iron of a proper size; and then make the thick end of the bone, first dipped in pitch, to go into it; after which let it be scraped, filed, and neatly whipped. However, the neatest rod may be thus made: get a thick white deal or fir-board, free from knots, and seven or eight feet long; let this be divided by a joiner into several breadths, and with his planes let him shoot them round, smooth, and taper. To one of these fasten a hazel rod, six or seven feet long, which may consist of two or three pieces; to the top of which fix a piece of yew, about two feet long, made round, taper, and smooth, and to the yew a piece of small, round, smooth whalebone, five or six inches long. The fir may be coloured by warming it at the fire, and with a feather dipped in aqua fortis, stroking it over, and chafing it into the wood, which will make it of a pure cinnamon colour.

It is found useful to have rings or eyes made of fine wire, and placed upon the rod from one end to the other, in such a manner as that when the eye is laid to one, you may see through all the rest; through these rings the line is made to run, which will thus be kept in a due posture; and you must have a winch or wheel fixed to the rod about a foot above the end, by which, whenever it is proper, you may give range to the fish. See *Angling*.

FISHING-WEEDS, or those used in the several fisheries at sea, or on the coast, are the *fish*, *cob*, *catch*, *digger*, *drift*, *robinet*, *fish-bow*, *fish*, *hooker*, *pearl-bait*, *smack*, *staid*, *hooker*, *trinder*, &c.

FISH-FONDS, reservoirs of water, for the breeding, feeding, and preserving of fish.

The quality of the pond, water, &c. proper for this end is scarce determinable by any certain symptom or rule; for some very promising ponds do not prove serviceable that way. One of the best indications of a breeding pond, is, when there is good store of rush and grazing about it, with gravelly shoals, such as horse-ponds usually have; and when a water takes thus to breeding, with a few milch and spawners, that is, males and females, two or three of each, a whole county may be stocked in a short time.

Eels and perch are of very good use to keep down the trout.

stock of fish; for they prey much upon the spawn and fry of bred fish, and will probably destroy the superfluity of them.

As for pike, perch, tench, roach, &c. they are observed to breed almost in any waters, and very numerously; only eels never breed in standing waters that are without springs; and in such are neither found, nor increase, but by putting in, yet where springs are, they are never wanting, though not put in. And, which is most strange of all, many say there is not in an eel the least token of propagation, either by milt or spawn; so that how they are produced is a question very mysterious. See EEL.

For fish-ponds, it is agreed, those grounds are best which are full of springs and up to be moorish, the one breeds them well, and the other preserves them from being stolen. The situation of the pond is also to be considered, and the nature of the currents that fall into it; likewise, that it be refreshed with a little brook, or with the rain-water that falls from the adjacent hilly ground. Add, that those ponds which receive the hale and dung of horses, and other cattle, breed the largest and latest fish.

Fish-ponds are not only a thing of convenience to great families, but may be made a very profitable article with the farmer, under due management. Watery and boggy land is often fit for no other use, and these are then a great improvement of it. Ponds made in dry grounds in the flat bottoms between hills, will also serve not only to supply the estate with water, but the profit of the fish that may be bred in them, is greater than many are aware of, and comes without any labour or expence.

In making the pond, observe that the head be at the lowest part of the ground; and that the trench of the flood gate or sluice have a good swift fall, that it may not be long in emptying on occasion.

The best way of making the head is by driving three or four rows of stakes about six feet long, and at about four feet distance from one another, the whole length of the pond-head; the first row of these is to be driven in four feet deep, that they may be very firm and secure; and if the bottom be not good, but be of a loose sand, some lime is to be added, which will harden into a sort of stone. The earth dug out of the pond is to be laid between these stakes and rammed hard down. Other rows of stakes must be added behind and over these, and the spaces filled up till the whole is as high and as thick as is necessary. The face of it must be made even and slanting, and there must be a wall left to carry off the superfluous water in floods, &c.

If the pond carry six feet of water, it is enough; but it must be made eight feet deep, to receive the freishes and rains that may fall into it.

It would also be advantageous to have shoals on the sides for the fish to sun themselves in, and lay their spawn on; beside, in other places, certain holes, hollow banks, shelves, roots of trees, islands, &c. to serve as their retiring-places. Consider further, whether your pond be a breeder; if so, never expect any large crop from thence, the greatness of the number of spawn overstocking the pond.

Carp and tench will live and thrive very well together in the same pond. Where pike are kept, there should be roach or some other quick breeding fish to supply them with food.

Some think this pike and tench may be kept in the same pond. They imagine that pike will not feed upon tench; but they are mistaken, for the pike is fonder of this than of almost any other fish. Ponds with clear gravelly and sandy bottoms are usually the best for breeding of fish, and foul water with muddy bottoms are the best for them to fatten in. Carp have been known to grow in one year from five to eighteen inches long in ponds where the water of the common sewers of any town have run into it.

The ordinary growth of a carp is not above two or three inches in that time, so that all the excess is to be attributed to the fatness of the water of the sewers. See CARP.

Reserve some great waters for the head-quarters of the fish, whence you may take, or wherein you may put any quantity thereof; and take care to have sluices, and other auxiliary waters, so that you may convey any part of the flock from one to the other, and lose no time in the growth of the fish, but employ the water as you do your land, to the best advantage. View the grounds, and find out some fall between the hills as nearly flat as may be, so as to leave a proper current for the water: if there be any difficulty in judging of such, take an opportunity after some sudden rain, or the breaking up of a great snow in winter, and you will plainly see which way the ground calls, for the water will take the true fall, and run accordingly.

The condition of the place must determine the quantity of ground to be covered with water. For example, we may propose in all fifteen acres in three ponds; or eight acres in two, and no less; and these ponds should be placed one above another, so as the point of the lower may almost reach the head or bank of the upper, which contrivance is no less beautiful than advantageous.

The head or bank, which, by stopping the current, is to raise the water, and to make a pond, must be built with the clay and earth taken out of the pan or hollow dug in the lowest ground above the bank; the shape of the pan is to be an half-oval, whereof the flat is to come to the back, and the longer diameter to run square from it.

All fish-ponds should be drawn once in three or four years, and the fish forced; if it be a breeding-pond, the smaller fish should be taken out to those other ponds with; and in feeding-ponds all the fish should be kept as nearly as may be of a size, for the larger and smaller never all thrive well together.

Flounders will both thrive and breed in any pond, especially in a clay pond, and will be much larger than in rivers.

Breams, herons, citers, water-rats, and teal-pulls, are all great destroyers of fish, and the ponds should be kept as clear as possible of them; but the greatest of all destruction in fish-ponds is occasioned by frosts.

To remedy this, some propose to break the ice and lay in pipes, straw, and other things, to give air to the fish; but all these fail when the ponds are foul; but when they are clean, the fish seldom suffer any harm, be the frost ever so long, though no holes be broke in the ice. The trench of foul water seems to be the occasion of the death of the fish, in this case of its being locked up by frosts, and not the want of air. The cleaning of ponds frequently is of great use as well on this as on many other occasions; and it is done at no expence, because the mud serving as manure to the lands, more than pays the expence of taking it out.

When the ground is boggy, and carts cannot come up to take the mud, it is best to cut the ponds long and narrow in form of moats, that it may be thrown out at one side by the labourers in clearing them; for if it require two toffes, the difference will be just the double price of labour.

FISSURE, *Fissura*, in Surgery, a longitudinal fracture of a bone; or a solution of the continuity of a bone, whereby it is only cloven or cracked.

Fissures are of two kinds; the one apparent, by the Greeks called *tyras* or *phagos*; and by the Latins, *fissura*; the other so small as not to be visible, called *typhlophagos*, or *capillary*, as resembling a thread.

The causes of fissures are falls, leaps, and contusions of the parts against hard bodies.

Fissures, especially in the cranium, either happen on the part where the stroke was given, or on the opposite part; that on the opposite part is called *contra-fissura*, or *contra-lyssa*, by the Greeks, *antepnos*, and the Latins, *contra-fissura*. See CONTRA-FISSURE.

Old men are more subject to fissures than young ones, because their bones are drier.

Fissures are difficult to be discovered; but they are the easiest cured of all fractures; though if they be not known, or be neglected, they bring on ulcers and caries, and in such case become very dangerous, so that there is frequently a necessity of having recourse to the severest operations.

The signs of a fissure of the cranium are bilious vomitings, vertiges, fluxes of the blood at the mouth or nose, dumbness, delirium, &c. If there be any fissure in the skull, the patient will feel a pain in the place, upon holding a firing between his teeth, while the surgeon pulls it strongly.

In such cases it is frequently necessary to perforate the cranium, to give a vent for the blood and fumes. See CONTUSION.

FISURES, in the History of the Earth, certain interruptions that horizontally or parallelly divide the several strata of which the body of our terrestrial globe is composed.

FISTULA, in Antiquity, an instrument of wood used in driving piles, and fired with two handles. It was either raised with pulleys fixed at the head of large beams, and then let fall again directly on the piles, or was wrought by the hand only.

FISTULA, in the Ancient Music, an instrument of the wind kind, resembling our flute or flageolet.

The principal wind instruments of the ancients were the *tibia* and *fistula*; though how these were constituted, or wherein they differed, or how they were played on, does not at present appear. All we know is, that the *fistula* was at first made of reeds, and afterwards of other matters. Some had holes, some none; some again were

single piece; others a combination of several; which the figure of the *Fistula*.

FISTULA, in Surgery, a deep, winding, cavernous ulcer, with a narrow orifice, and opening thence into a particular bottom, seated in the cellular membrane, and generally yielding a thin and viscid matter.

Fistulae differ from simple Ulcers in this, that the former are cavernous, as both in their progress, and the latter not. They attack all parts of the body without exception; but particularly the arms, forearms, ischiorectal, thorax, &c. The general cause of *Fistulae* is some abscess or ulcer, which, either being neglected, or having been ill treated, converts to be callous, the orifice being at first lined or incrustated therewith, and at length the whole heals.

In the first stage of a *Fistula*, before they are become callous, the most effectual way of curing them is by an incision to the bottom, whenever it can be safely done, and afterwards detaching and consolidating them. They should then be gently pressed from the bottom towards the orifice in order to discharge the secret matter; for which purpose a camphor or small slip of plaster wrapped up in lichen form should be applied to the bottom of the *Fistula*, after it has been cleaned, and proper dressings have been used, and dressed with lint, plaster, and bandages; and if this method fails, recourse must be had to the manual operation; because, by laying open all the sinuses of the *Fistula*, proper passages are made for the discharge of the corrupted matter, and suitable remedies may be conveniently applied to the several dilated parts. The ancients gave the name *Fistula* to this kind of ulcer; from the resemblance they bear to account of their depth to a flute or pipe, called by the Latins *Fistula*.

FISTULA, in Anatomy, is a *Fistula* opened in the anus or fundus recti. Others form several four kinds, viz. the *perianthematic*, which is opened externally, but not into the rectum; the *perianthematic*, which has an orifice into the rectum, but none outwardly; the *external*, which opens both ways; and the *canalicular* or that with several sinuses, which discharge themselves into one common cavity, which is the fundus, and, as it were, the reservoir of them all.

Others, as Willman, reduce *Fistulae* in *ano* into two classes. The first are those arising from a phlysis; these are very painful, and difficult to cure, enter deep among the interstices of the muscles, and form various sinuses or sinuses; which, the more remote they are from the anus, the worse they are, because they do not allow of being cut.

The second owe their origin to an internal hæmorrhage, or extravasation, between the coats of the rectum, and have a small perforation near the circumference of the anus, whence they yield a thin faeces or stool without pain, which in time brings on itching and excoriation; and the orifice at length becomes callous, and are sometimes closed, and sometimes open again.

Some *Fistulae*, if they do no harm by the copiousness of the flux, the flux, or the like accidents, are a benefit to nature, because they carry off caustic humours, and ought not to be cured, but kept open. The fresh, simple *Fistulae* may be cured without danger.

The chief way is by cutting, where that may be done without damage to the muscle of the anus, which might occasion an involuntary discharge of the excrement.

The cut is either performed with a thread or with a cutting instrument.

The method by ligature is to take a thread of silk or horse hair, and threading it in the eye of a leaden or tin probe, to introduce the end of the thread into the *Fistula*, and with the forefinger of the other hand, anointed with oil of roses, and thrust up into the anus, to lay hold of the end of the probe and draw out the thread, and then tie the two ends together as tight as the patient can well bear it; and thus by tying it afresh, somewhat tighter every day, it will cut quite through, and the *Fistula* will be laid open; after that the callus must be consolidated, and the ulcer healed. Mr. Pott advises the operation by incision, to be performed in the following manner: In a curve, probe-pointed knife with a narrow blade be introduced into the sinus, while the surgeon's forefinger is in the intestine; where there is no opening in the lining, the least degree of force will thrust the point of the knife through, and thereby make one; if there be an opening already, the same point will find and pass through it. In either case, it will be received by the sinuses, and will thereby be prevented from deviating, and being thrown out by the fist finger, must necessarily divide all that is between the orifice of the *Fistula* and the corner of the anus. When the operation is finished, a soft cloth of fine lint must be introduced down the sinus of the wound, and the rest of the ulcer end with the finger. He observes, in his remarks on this disease, that it is much more common than is generally thought.

gined; and that a mere object or collection of matter, without *Fistula* or callosity, is often mistaken for it. A total suppression of urine is a symptom frequently attendant on the formation of an abscess near the rectum and bladder; for the relief of which, recourse is often had to the catheter; but as this complaint is spasmodic, he advises evacuation and anodyne relaxation, such as emollient, gentle cathartics, leucopurium, bladders of hot water applied to the pubes and perineum, and clysters composed of warm water, oil, and opium, as the true, safe, and rational method of relieving it.

FISTULA, in the Epilepsia. We have in the Lond. Med. ON. vol. ii. p. 273. a case of this kind, related by Mr. Ingham: a man of thirty-five years of age hurt his testicles by a fall, a suppuration followed, and the matter was discharged externally. After this, the swelling being reduced by means of emollient and resolvent cataplasms, a *Fistula* was discovered in each epididymis: a fine probe-director was then introduced into the sinus of the left testis, which was cut open through its whole length; after which all the indurated parts and the diseased skin were cut off, the same was done to the other testis, and a large portion of the lower part of the epididymis was extirpated. A suppuration came on in five or six days, and the patient was cured by the common method of dressing in three weeks, so that the functions of the testes were properly executed.

FISTULA lachrymalis is a *Fistula* in the greater canthus of the eye; this is frequently conformed with *MOLE*. It is a little deep callous ulcer in the greater canthus, or the place of the glandula lachrymalis. It usually begins with an abscess, called *ostium*, which in time produces an ulcer, called *ostium*, which afterwards degenerates into a *Fistula*. When pressed with the finger it yields a stinking matter, or unlike the yolk of an egg; and the corrosive humour, finding or making itself a passage, there enters a perpetual oozing. Sometimes the os thinnates itself is corroded, and rendered carious by it, in which condition it is supposed to be only curable by an actual cautery; sometimes it becomes cancerous; and then Rivecourt directs all medicines to be laid aside.

This malady is seldom or ever cured by any other means than external and surgical operation; and the operator must be guided by the various circumstances of the disease. If the lachrymal sac and its integuments be distended with only a small degree of inflammation and chinkiness of the skin, a single incision, made with a small sharp round-pointed knife, and continued from the upper to the lower extent of the tumor quite down into the cavity of the eye, will sometimes be found sufficient, for the purpose of applying proper dressings to the bottom of the diseased sac. Where the skin is much lifted up and grown thin, and discoloured from a large quantity of matter that has long been deposited and confined in the sac, or where the integuments have burst, become callous and livid; it will be found expedient, in the instant, to remove an oval piece of the integuments and sac, by making the incision equally long with the distended skin, and of such a breadth as will admit the removal of the greater part of the diseased integuments and sac; and, in the second instance, the whole of the callous integuments, together with the upper part of the lachrymal sac, must be cut away; by these means every advantage which art can procure will be obtained for the treatment of an hollow ill-conditioned sac. Warner, &c. on the Eye, 1775, p. 19.

Mr. Lamourier proposes to abridge the operation of this *Fistula lachrymalis*, and to procure a passage for the tears into the nose. The os begins to be laid bare at the first incision, and pierced with a pair of strong, sharp-pointed, and crooked forceps, and then the operation dilated by opening the forceps. After the inflammation is over, a piece of small wax-candle, shaped like a tent, is to be introduced by the wound into the nose, and secured by the other dressings. He continues the use of this bougie till the passage is made callous, and out of hazard of returning; after which he allows the external wound to cure. Medie. Ess. Edin.

Dr. Hummel has communicated some thoughts on the operation of the *Fistula lachrymalis*, and proposes, that no tent should be put into the perforation of the os nasum, because the tears will of themselves keep it open. Phil. Trans. N. 437, 438. or Abstr. vol. 18, p. 121, Sec. Mr. Pott concludes the cause for the tears from the *Fistula lachrymalis* is a *Fistula*, the longer leg of which the nasal sac, and therefore thinks that a shorter passage made through the os nasum would not carry away the tears; for which reason he would have no more the nasal passage forced open in the *Fistula lachrymalis*, and a small bougie kept in it till healed. Mem. Acad. Sursc. 1754.

A French fargeon, named Anel, found out a new way, viz. by putting a probe and syringe of an inconceivable fineness through the puncta lachrymalia into the sacculus lachrymalis. See *Tab. II. Surgery*, fig. 20.

Mr. Warren has proposed a method of clearing the obstructed lachrymal duct, by leaving in it a metal tube, and healing the external wound over it. In order to introduce the tube properly, he has contrived a kind of style fitted to it. For the description and representation of both, see his *New and easy Method of applying a Tube for the Cure of the Fistula Lachrymalis*. 4to. 1783.

The expediency of perforating the os unguis has been a subject of dispute, especially when it does not appear to be carious, known by being directed of its periosteum. But Mr. Warner observes, from his own experience, that there is no curing a discale of this kind without destroying the os unguis, at least in part, even when the bone is not diseased and carious. The necessity of breaking through this bone arises from the diseased state of the hinder part of the tuck and periosteum; the os unguis is so thin as to require very little force in breaking it; a passage may be made through it into the nostril with the edge of the incision-knife, and so effectually as not to require the assistance of any other instrument besides a large probe or bougie, bent and fitted to the size and direction of the orifice, and inclining downwards into the nostril. The perforation of the os unguis is sometimes known by its cracking, and by a discharge of blood, which in a small quantity trickles down the nostril. If a trocar be used for this purpose, it should not be too much curved; otherwise it will be brought too much forwards and outwards, inclining to the nasal process of the superior maxillary bone, which is thick and strong, and cannot be broke without very great force. When the perforation is made, Mr. Warner immediately introduces a small long sponge tent through the wound into the nostril, and continues the use of the tent for ten or twelve days, or longer; together with thin soft injections for keeping the parts clean and open whenever the wound is dressed, which is generally at first necessary to be done twice a day. When the opening through the os unguis is sufficiently confirmed, known by being able to introduce into the nostril a small bougie, or a large ductile probe, without resistance; he uses soft tents of lint for a week or ten days longer, and then dresses the wound to the bottom, sometimes with plaasters of derivative elements, and sometimes with dry lint only, occasionally touching the frowning and loose flesh with the lunar caustic, which he prefers to vitriol. He afterwards dresses the wound almost superficially with lint, or ceratum euphoracum spread upon lint, till the parts are healed and the cure is usually completed in five or six weeks.

Some have recommended preure upon the integuments and subjacent lachrymal sac, by means of inflammation adapted to this purpose, in incipient abscesses and dissections of these parts; but Mr. Warner observes, that he has seldom or ever found such an application of service. The best practice in such case is that of one of the fingers applied to the interior part of the tumor when the sac is loaded and discolored; by this simple treatment, joined with purgative medicines, and a moderately cooling and astringent eye-water, the disease has been checked, and may possibly be cured. In this disease, opacities occasionally administered, evacuations by bleeding, gentle purges or clysters, and antiphlogistic medicines, joined with a proper regimen in diet, ought to be continued till the inquietude, spasms, pain, and symptomatic fever, arising from the severity of the operation, are removed. In many instances it will be necessary to use alteratives; sometimes of the mercurial, and sometimes of the antimonial kind, given alone or joined with antiseptics, as the bark to sustain the decoction, or infused with common or simple lime-water, the aqua calcis magis, or mineral compunds of the London Dispensatory, or decoctions of equal parts of Adonis and Galipassula. Warner on the Eye, p. 12-20.

FISTULA IN PERINEO is usually the consequence of lithotomy, or making a puncture near the urethra, or from a severity of the prostatic gland, or from a wound or ulcer, the lips of which become callous, and form a *fistula*, through which the urine is prematurely discharged. The circumstances attending different cases of this kind are so various, that only general rules can be laid down for a cure. Accordingly, the outward opening must be enlarged by cutting away the callous lips, or destroying them by caustic: in some cases it will be sufficient to introduce a bougie into the urethra for discharging it. Le Dran observes, that though there are several fistulous orifices, and several callousities in the perineum, and when the water passes off through the natural passage in a small stream, the chief remedy will be the introduction of bougies; and that as this canal is enlarged, the external

orifices are lessened and healed, and the callousities softened. See Le Dran's operations.

FISTULA PALMARIS, in *Anatomy*, a term used by some writers for the *aperta arteria*.

FISTULA SACRA, in *Anatomy*, is that part of the back-bone which is perforated.

FISTULA URETHRIS, in *Anatomy*, the same with the urethra.

FISTULAE, or **FISTULOUS**, is applied by the surgeons to wounds and ulcers which degenerate into fistulas.

FISTULAE is also applied to the leaves of plants which are round and hollow within; as the leaves of leeks, &c.

FISTULAE FLORIS, among Herbarists, are those made up of many small, long, hollow flowers, like pipes.

FIX, in *Medicine*, an accels or **PAROXYSM**.

Dr. Cheyne is of opinion, that fix of all kinds, whether epileptic, hysterical, or apoplectic, may be cured solely by a milk diet, of about two quarts of cow's milk a day, without any other food. Cheyne, *Mat. Med.* of Curing, p. 265. See **CONVULSION**.

FIX is *very reflection and easy transgression*. See **LIGHT**.

FIX of the matter. See **HYSTERIC AFFECTION**.

FITCHEL, or **FITCHER**, in *Heraldry*, is when the lower part of any crest is sharpened into a point fit to fix into the ground.

Thus, he bears azure, a cross potent *fisher*. See *Tab. Heraldry*, fig. 21.

The origin hereof McKenzie ascribes to the primitive Christians, who used to carry their crosses with them wherever they went; and when they stopped at any place in a journey, fixed them in the ground.

FITCHES, a name given by our farmers to a sort of pulve which they sow in their fields. Many suppose it is the same with the tare, but erroneously; it is the which or chick-pea of authors. There are two principal kinds of this use among us, the winter and the summer *fish*. The one is sown before winter, and shades the extremity of it; the other is sown in spring. They are propagated in the same manner as peas, and they make a very good and nourishing food for cattle, whether given in straw or threshed out. They are sometimes sown only to improve the land. In this case they are to be plowed in, just as they are beginning to blossom, and in this manner they finely enrich a tough stiff clay.

FICHE, a name used in some places for the **WEAVER**; called also the *fishal* and the *fisher*. See **POLK**.

FIXING-OUT, in *Naval Language, the act of providing a ship with a sufficient number of men, to navigate and arm her for attack or defence; as also of furnishing her with proper masts, sails, yards, ammunition, artillery, cordage, anchors, and other naval furniture, together with sufficient provisions for the ship's company. See **CARR**.*

FIX, a French term, literally denoting *fix*; sometimes given by way of addition to the natural form of the kings of England; as James *Fix-Roy*, duke of Grafton, &c. **FIXED-GOLD**, *Grasso*, in *Heraldry*, is used by such as would introduce a blazon by herbs and flowers instead of metals and colours, to signify **VERT**, or **GREEN**.

FIXES, among *Foreriers*. See **VIVES**.

FIXATION, the act of fixing, or of rendering a thing firm and fixed.

FIXATION is applied in the general to any process that fixes and binds together what, of its own nature, is volatile; and enables it to sustain the loss of fire for some considerable time.

Geber defines *fixation* an operation whereby a volatile thing, i. e. a thing that cannot endure the fire, is rendered capable of enduring it. In the general, *fixation* is the changing of a volatile body into a fixed one.

FIXATION, among *Alchemists*, denotes a peculiar preparation of mercury, whereby it is to be put in a condition to bear the fire without evaporating, or the hammer without flying or separating.

The alchemists hold, that if they had the true secret of fixing mercury without the addition of any foreign body heavy and sold in gradient, they could make gold, or at least silver.

M. Homberg had a long process of many months to prepare an oil from the fecal matter of human excrements; which, he imagined, would have fixed mercury into silver; but it failed.

FIXED AIR. See **AIR**.

FIXED SALTS, in the general, are those which neither the fire nor any corrosive has such effect on, as to reduce or resolve them into their component elements; i. e. absolutely to destroy them.

Chauvin holds it not sufficient to denominate a body *fixed* that it can withstand the fire or any true agent, but it should withstand all. He contends, that *fixity* should not be restrained, as it usually is, to an exemption from evaporation, but from destruction, or resolution into primary elements: in this sense, gold, precious stones, and

phus, and even sulphur, and mercury itself, are properly *fixed bodies*; for mercury and sulphur retain their nature notwithstanding their evaporation.

The chemists divide all natural bodies into *fixed* and *volatile*; i. e. such as bear the utmost force of the fire without dissipating or spending themselves in fumes, and such as do not.

Of *fixed bodies*, the principal are platinum, gold, silver, precious stones, particularly the diamond, salts, &c.

Of all metals, gold and silver alone are fixed; i. e. on remaining a long time exposed to the most intense flame, they show no diminution of their weight.

Whence this property should arise is difficult to say. If the reader is not contented with the causes enumerated under *FIXITY*, he may add the following one from Boerhaave, viz. the homogeneity and equality of the parts.

The parts, e. g. of gold being all homogeneous, and equal, will equally sustain each other, and leave equal pieces between them; through which pores, when fused, the fire finding an easy, equal passage, goes off, without carrying any thing of the metal with it; or rather the particles of gold being of all others the most solid and heavy (as appears from the weight of this metal) and of all others the most strongly united or bound together (as appears from the immense ductility of this metal), the force of the fire is not sufficient to overcome so powerful a resistance: the solidity of the particles, and their freedom from air, prevents their being carried, or set farther apart, which might lessen their specific gravity, and diminish their *vis obliqua*; so that what has the chief effect in the raising of fumes and vapours, viz. the rarefaction or expansion of the body being here precluded, the metal maintains its natural weight and tendency to the centre.

Mr. Boyle, the prince of Mirandola, M. Homburg, and others, have made numerous experiments on gold, silver, &c. to see how far their fixity extended; in these, pure gold, kept in an intense heat for two months, lost nothing sensible of its weight; *SILVER*, under the like circumstances, and in the like time, lost one-twelfth part of its weight; but Mr. Boyle attributes this to the metal's not being fine and pure.

Inlaid, by the great burning-glasses of Mess. Tschirnhausen and Vilette, the most *fixed bodies*, as gold itself, are rendered volatile, and lose of their weight; so that there is no body in all nature absolutely *fixed*.

FIXED line of defence, a line drawn along the face of the bastion, and terminating in the curtain. See *DEFENCE*.

FIXED nitre, a preparation of saltpetre, made by fusing it in a crucible, and then infusing it, with throwing in a few coals; and thus again and again, till no more flame or detonation arise; then, letting it cool, they pulverise and dissolve it in water, and afterwards evaporate it into a fine white salt, which serves to draw the tinctures out of vegetables. This salt, *per deliquium*, yields what they call the *liquor of fixed nitre*.

FIXED salts are those extracted, or gained from bodies by calcination and solution. See *SALTS*.

They are called *fixed*, because the fire was not able to sublime or raise them; as those carried off in the course of calcination by the vehemence of fire are called *volatile*.

The ashes of all plants yield *fixed salts*. See *LIXIVUM*.

FIXED signs of the Zodiac, according to some, are the four Taurus, Leo, Scorpio, and Aquarius.

They are so called because the sun passes them respectively in the middle of each quarter, when that season is more fixed and *fixed* than under the sign which begins and ends it.

FIXED stars are such as constantly retain the same position and distance with respect to each other.

By which they are contra-distinguished from erratic or wandering stars, which are continually shifting their situation and distance.

The *fixed stars* are what we properly and absolutely call STARS; the rest have their peculiar denomination of PLANET and COMET.

FIXEN, among *Sportmen*. See *FIXEN*.

FIXES is a name given by the workmen in gold and silver to a solution of silver, from its use in carrying down and fixing the heterogeneous ashes mingled with aqua fortis.

FIXING sulphur. See *SULPHUR*.

FIXITY, or *FIXEDNESS*, in *Philosophy*, the quality of a body which decomposes and renders it fixed; or a property which enables it to endure the fire and other violent agents.

According to Chuvius, *fixity* consists in this; that the component principles of the body are so closely united or cohered (so to speak), and are mixed in such proportion that they cannot easily be divided either by fire or any other corrosive menstruum, or their integral parts separated and carried off in vapour; for a body may be said to be fixed in two respects:

First, When, on being exposed to the fire, or a corrosive menstruum, its particles are indeed separated, and the body rendered fluid, but without being resolved into its first elements. The second, when the body sustains the active force of the fire or menstrua whilst its integral parts are not carried off in fumes. Each kind of *fixity* is the result of a strong or intimate cohesion between the particles mixed.

FIXITY, or *FIXEDNESS*, in *Chemistry*, is, in a peculiar manner, used for the affection opposite to *VOLATILITY*; i. e. the property whereby bodies bear the action of the fire, without being dissipated in fumes.

The principle causes of *fixity*, or the qualifications that contribute most to the rendering a body fixed, according to Mr. Boyle, are, 1. That its corpuscles be singly of a certain proportionable bulk, too big and unwieldy to be carried up by heat, or buoyed up in the air. 2. That they have also a proper degree of weight or solidity. 3. That their figures be such as unfit them for evaporation or flying off; some being branched, others hooked, &c. so that being entangled with one another, they cannot easily be extricated, loosened, and separated. To these may be added a fourth circumstance, viz. the narrowness of the particles, and their being contiguous in a great many points, or large extent of surface, which produces a stronger force of attraction and cohesion.

FLACCIDITY, in *Medicine*, &c. a disorder of the fibres or solid parts of the body, opposite to rigidity.

The too great *flaccidity* of the parts is cured by cardiacs, exercise, friction, a dry warm air, proper food, &c.

FLAG, a general name, including colours, standards, ancient, banners, ensigns, &c. which authors frequently confound with each other.

The fashion of bearing the *flags* pointed or triangular, which now obtains, Roderic Toletanus assures us, came from the Mahometan Arabs or Saracens, upon their seizing of Spain, before which time all the ensigns of war were square, stretched, or extended, or cross pieces of wood, like church-banners, on which anciently they were called in Latin *varia*, q. d. *velia*, a *veli diminution*, as is remarked by Isidore.

The pirates of Algiers, and those throughout the coast of Barbary, are the only people who bear an hexagonal *flag*. It is gules, charged with a mosque head, coifed with its turban, &c. though this be expressly contrary to their law, which prohibits the making any image or representation of a man, founded on an opinion, that they who make them shall be obliged at the day of judgment to find souls for them, and that in defect hereof they shall be damned. But this portrait which they carry is that of Hali, Mahomet's son-in-law, to whose party the Africans all retain, who ordered that his effigy should be expressed on their *flags* and standards, believing himself so formidable to the Christians, that the bare sight of his image would carry undoubted victory over them. Leucivius.

FLAG, in the *Military Art*, are small banners of distinction stuck in the baggage-waggons of the army, to distinguish the baggage of one brigade from another, and of one battalion from another, that they may be marshalled by the wagon-master-general according to the rank of their brigades, to avoid the confusion that otherwise might arise.

FLAG is more particularly used in *Sea-language*, for the colours, ancient, standards, &c. borne on the top of the masts of vessels, to notify the quality of the person who commands the ship, of what nation it is, and whether it be equipped for war or trade.

In the British navy *flags* are either red, white, or blue, and are displayed from the top of the main-mast, fore-mast, or mizen-mast, according to the rank of the admiral. The first *flag* in Great Britain is the Royal standard, which is only to be hoisted when the king or queen are aboard the vessel. The second is that of the anchor of hope, which characterizes the lord high admiral, or lord commissioners of the admiralty; and the third is the union *flag*, in which the crosses of St. George and St. Andrew are blended: this last is appropriated to the admiral of the fleet, who is the first military officer under the lord high admiral.

The admiral or commander in chief carries his *flag* on the main-mast; the vice admiral carries his on the fore-mast; and the rear-admiral his on the mizen-mast.

The next *flag* after the union is that of the white squadron, at the main-mast; and the last which characterizes an admiral is the blue, at the main-mast-head. For a vice-admiral, the first *flag* is the red; the second, the white; the third, the blue, at the *flag-staff* on the fore-mast. The same order proceeds with regard to the rear-admiral, whose *flags* are hoisted on the top of the mizen mast; so that the lowest *flag* in our navy is the blue on the mizen-mast. When a council of war is held at sea, if it be on board the admiral, they hang a *flag* on the

the main-branch: if in the vice-admiral, in the fore-branch, &c. if in the rear-admiral, in the mizen-branch. The *flag* borne on the mizen are particularly called *pollants*. See *Mast*, &c.

The *flag* of the French nation is blue, charged with a white cross, and the arms of France.

Beside the national *flag*, merchant-ships frequently bear lesser *flag* on the mizen mast, with the arms of the city where the master ordinarily resides, and on the fore-mast with the arms of the place where the person who freighted them lives. See *Table of Flags*.

FLAG, is *before and the*, is to put out or hang abroad the *flag*.

FLAG, is *to have out the white*, is to all quarter; or it flows when a vessel is arrived on a coast that it has no hostile intention, but comes to trade, or the like. The red *flag* is a sign of defiance, and battle.

FLAG, is *to own, or strike the*, is to pull it down or take it in, out of respect or submission, when a weaker party meets a more powerful one.

By an ordinance of Philip II. king of Spain, 1565, the captains are peremptorily commanded to perish rather than lower their royal *flag* when once hung out.

The way of leaving vanquished ships in triumph is, to tie the *flag* to the bowsprit, or the gallery in the hind-part of the ship, and let them hang down towards the water, and to tow the vessels by the stern. It was thus the Romans used those of Carthage, as Livy relates.

FLAG-officers, those who command the several squadrons of a fleet; as admirals, vice-admirals, and rear-admirals.

The *flag-officer* in our navy, is the admiral, vice-admiral, and rear-admiral, of the white, red, and blue.

FLAG-ship, a ship commanded by a general or *flag-officer*, who has a right to carry a *flag*, in consequence of the secondary vessels under the command thereof.

FLAG-stones, are the flaves set on the heads of the top-galant masts, serving to let fly and unfurl the *flag*.

FLAG, in *Natural History*, a genus of hard and rough stones, composed of a visible grain of a laminated structure, and splitting only horizontally or into plates.

M. de Colla distributes them into alkaline *flag*, or laminated sand-stone, and such as are not acted upon by acids. Of the former kind are the ash-coloured *flag*, the laminae of which are numerous and very visible, and so thin as sometimes not to exceed the thickness of brown paper; so that in a piece of half an inch thick seven or eight perfect laminae are often discernible: this, by being burnt, becomes extremely friable, and of a white colour.

It is dug in several parts of the kingdom, and is frequently used to cover houses instead of tiles, though it is very unfit for the purpose, as it bears the weather badly, and crumbles after frosts: and the ash brown-coloured *flag*, of a more compact texture, and heavier than the former, though composed like that of an irregular grain cemented by a coarse spar; this becomes friable by being burnt, but suffers no change of colour: there are quarries of it at Barford in Oxfordshire, where it is used to slate houses, for pavements, &c. Neither this nor the former will strike fire with steel.

The *flag* or *plate stone* common in Northumberland and some of the neighbouring counties is called by some *Car-life* and *white flag*. It is a white foliaceous stone, easily splitting into thin plates, and is full of small sponges of a fine glittering tale. It is also common in Yorkshire and the neighbouring places; it varies a little in colour, being sometimes grey, sometimes brownish, and sometimes merely whitish. Its strata are very thick, but they easily separate into laminae of about half an inch thick, and the workmen seldom attempt to split it any thinner; the upper strata, however, grow gradually thinner, and the bottom ones are so thick as not to be used for slates. These they raise, however, and use for rannets, fates, the pavements of floors, and cisterns for water.

The *Stran-feld slate* is of a pale brownish colour, very hard and heavy, and its strata or the surfaces of the laminae are always thick set with small bristles, but few or none are imbedded in its solid substance: it burns to a brownish colour. This *flag-stone* is dug out of the quarries at Stran-feld in Oxfordshire, in the winter season, and laid in large masses in the open air till summer, and thus rendered flexible: the plates into which it is split are the common fluting-stone in these parts: the upper stratum of the quarries is a soft gritty laminated stone, violently fermenting in aqua fortis, used as a sort of whet-stone; neither of these two last species will readily strike fire with steel. The pale, whitish, brown-coloured *flag* is of a compact and uniform structure; and the grain that forms it is so intimately blended with marine bodies, and saturated and cemented to such a degree with fine sparry matter, that the gritty texture of the stone is hardly visible. No part of it is changed by burning, except the shells that are lodged in it. It will not strike fire with steel. There are several strata of this stone

in the neighbourhood of Bath, where it is used as stone for covering houses. The deep, dusky, lead-coloured *flag* is extremely hard and heavy, of a compact texture, composed of a small grain, which is cemented together by an earthy, sparry, and crystalline substance: its flat surfaces are beset with great numbers of fine talcy particles; the plates are generally very regular and thin, not exceeding the tenth part of an inch in thickness, and cohere so firmly together as not to be easily separated. This stone readily strikes fire with steel, and, being burnt, acquires a reddish brown colour. It is dug in several parts of Italy, and much used in building. The first, second, and fifth species above mentioned are destitute of any brightness; the fourth, however, is very bright and glittering. Of *flags* which are not acted upon by acids, there are the following species: the *flag* of fallow white colour, which is composed of a large irregular crystalline grain cohering loosely together, and cemented with a terrene crystalline substance: the flat surfaces of the plates are covered with great quantities of small sponges of silver tale, which render them very bright and glittering. This stone is very heavy, and gritty to the hand, and the laminae are generally very regular and thin; a *flag* of two inches thick, having often fourteen or fifteen plates; it will not strike fire with steel: when burnt, it acquires a clearer white colour, with a slight reddish hue, and becomes very friable. It is dug in several parts of the kingdom, and used much as slate, for pavements, &c.

The bright and glittering *flag* is the hardest stone of this genus, and generally variegated with white and purple, and often the plates have one of these colours only. It is of a compact texture, and thickly spangled with small laminae: it strikes fire with steel, and acquires a paler colour by being burnt. It is much used in Italy, where it is dug for pavements. The brown coloured *flag* is composed, like the others, of an irregular grain, cemented by a crystalline substance; it is moderately hard and heavy; its flat surfaces are covered with small spangles of a silvery tale, and its laminae are thin and numerous: it burns to a pale reddish colour. It is dug in England, and very commonly in Sweden, but not applied to any particular use. De Colla's Fossils, p. 144-148. Hill's Hist. of Fossils, p. 433, &c.

FLAG, or *FLAG-flower*, in *Botany*. See *LAURE*.

FLAG is also used for a kind of rusted lead, as well as for the upper part of turf pared off to burn.

FLAG, *corn*, in *Botany*, *filicula*, a genus of the *triandria monogamia* class. Its characters are these: the flowers are included in sheaths; the petal of the flower is cut into six parts, and form a short incurved tube with their base; they have three awl-shaped stamens, which are inserted into every other petal. The perianth is fringed below the flower, which afterward becomes an oblong, swelling, three-cornered capsule with three cells, filled with roundish seeds. Miller reckons six species.

The root of the common *serpyllor* or *gladiolus* is accounted disjunct, and good in malignant and pellential cases.

FLAG, *joint-fentled*. See *ACORUS*.

FLAHS, in *Falconry*, are the feathers in a hawk's wing near the principal ones.

FLAG-worm, a worm so called from being found in sedgey places.

FLAGELLANTES, a sect of wild fanatics who chastised and disciplined themselves with whips in public.

The sect of the *Flagellantes* had its rise in Italy in the year 1260; its author was one Rainier, a hermit; and it was propagated from hence through almost all the countries of Europe. It was in all probability no more than the effect of an indolent zeal. A great number of persons of all ages and sexes made processions, walking two by two with their shoulders bare, by which they whipped till the blood ran down, in order to obtain mercy from God, and appease his indignation against the wickedness of the age. They were then called the *severus*; and having established a superior, he was called the *general of the severs*. Though the primitive *Flagellantes* were exemplary in point of morals, yet they were joined by a turbulent rabble, who were infected with the most ridiculous and impious opinions; so that the emperors and pontiffs thought proper to put an end to this religious frenzy, by declaring all devout whipping contrary to the Divine law, and prejudicial to the soul's eternal interest.

However, this sect revived in Germany towards the middle of the next century, and rambling through many provinces, occasioned great disturbances. They held, among other things, that flagellation was of equal virtue with baptism, and the other sacraments; that the forgiveness of all sins was to be obtained by it from God, without the merits of Jesus Christ; that the old law of Christ was soon to be abolished, and that a new law enjoining the baptism of blood to be administered by whipping

ping was to be substituted in its place: upon which Cle-
ment VII. by an injudicious as well as unphilosophical policy,
thundered our anatomists against the *Flagellantes*, who
were burnt by the inquisitors in several places; but they
were not easily exterminated. They appeared again in Thur-
rings and Lower Saxony, in the fifteenth century, and
rejected not only the sacraments, but every branch of
external worship, and placed their only hopes of salva-
tion in faith and flagellation, to which they added other
strange doctrines concerning evil spirits. Their leader
Conrad Schmidt and many others were committed to the
flames by German inquisitors, in and after the year 1512.
Mether's Eccl. Hist. vol. iii. p. 94, &c. 266 and 277,
&c. Esp. 8vo. edit. 1756.

FLAVELARIA, in Botany, a genus of the *bracteata tri-*
petala class, without any corolla: the calyx is divided into
five segments, and the fruit is a berry containing a single
seed.

FLAGELLATION, *expiation*, a voluntary discipline or
penance, frequently practised by the ancient penitents.
See DISCIPLINE.

The punishment of *Flagellatio* prohibited all public *flagella-*
tion by an act of 1601. See FLAGELLANTES.

FLAGELLATION is a term more peculiarly appropriated to
the sufferings of Jesus Christ, when whipped and scourged
by the Jews: from the Latin *Flagellatus*, a scourge or
whip.

We say, a painting of the *Flagellatus* or, simply, a
Flagellatus, to denote a picture or print representing this
moment inflicted on the Saviour of the world.
In this sense we say the *Flagellatus* of such a painter,
&c.

FLAGEOLET, or **FLAJOLET**, a kind of little flute; or
a musical instrument of the flute kind, used chiefly by
the shepherds and country people.

It is usually made of box, or some other hard wood,
sometimes of ivory. It has six holes or flaps beside that
at bottom, the mouth-piece, and that behind the neck.
The union of the *flagelet*, according to the scale exhibited
by Mætemius, is two octaves from *g* *sol* *re* *ut* *up* *ways*.

FLAIL. See THRESHING.

FLAIL, in Sea-language. The seamen say that the work
done *flail-oor*, when a ship being hauled in near the
water, so that the work hangs over a little too much,
and thus is let out broader aloft than the due proportion
will allow.

FLAIRS, in Ichthyology, a name given by some to the
ventral, *apex* of the pike.

The ancient Greeks called this *avot*, when they spoke
of the male, and when of the female, *FAVE*.

FLAIRING, in Sea-language. See FLAIR.

FLAKE, in the Coal-trade, a sort of scabbard or platform,
made of hurdles, and supported by stanchions, and used
for drying coal-fish in Newfoundland. These *flakes* are
usually placed over the flumes of fishing-labours.

FLAKES in Gardening, a name given by the florists to a
sort of carnations, which are of two colours only, and
have very large fringes, all of them going quite through
the leaves.

FLASKS, white, in Painting, is lead corroded by means of
the pressing of grapes, or a cerule prepared by the acid
of grapes. It is brought here from Italy, and for tur-
pessies, both with regard to the purity of its whiteness and
the certainty of its standing, all the cerule or white lead
made with us in common. It is used in oil and varnish
painting for all purposes, where a very clean white is re-
quired. The white *flask* should be procured in lumps
as it is brought over, and levigated by those who use it,
because that which the columnen fell in a prepared state
is levigated and mixed up with starch, and often with
white lead, and worse compositions.

FLAMBEAU, or **FLAMBOY**, a luminary made of several
thick wicks, covered over with wax, serving to burn at
nights in the streets, as also at funeral processions, illu-
minations, &c.

Flamboy differ from links, torches, and rapers. See
TYPIC.

They are made square, sometimes of white wax, and
sometimes of yellow; they usually consist of four wicks
or branches near an inch thick, and about three feet
long, made of a sort of coarse hempen yarn, half twisted.
They are made with the laddle, much as torches or rapers
are, viz. by first pushing the melted wax on the top of
the several disposed wicks, and letting it run down to
the bottom; and they repeat twice. After each wick
has thus got its proper cover of wax, they lay them to
dry their rot them on a table, and to join four of them
together by means of a red hot iron.

When joined, they pour on more wax till the *flamboy* is
brought to the size requisite, which is usually from a
cubit and a half to three pounds.

The last thing is to finish their form or outside, which

they do with a kind of polishing instrument of wood by
running it along all the angles formed by the union of
the branches.

The *flamboy* of the ancients were different from ours.
They were made of woods, dried in furnaces, or other-
wise. They used divers kinds of woods for this purpose;
the wood most usual was pine. Pliny says, that in his
time they frequently also burnt oak, elm, and hazel.
In the seventh book of the *Azied*, mention is made of
a *flamboy* of pine; and Servius, on that passage, re-
marks, that they also made them of the cornel-tree.

FLAMBO, in Natural History, a name given by some to
a long anguliform lish, a species of the *temia*, called
CATAGIRO.

FLAME, the brightest and fullest part of the fuel, ascend-
ing above it in a pyramidal or conical figure.

Flame seems to be the smoke; i. e. the fumes or volatile
part of the fuel, greatly rarefied, and at last kindled or
beared red-hot. By this great rarefaction, the matter be-
comes so light as to be raised with great velocity into the
air; and by the pressure of the incumbent atmospherical
fluid, it is kept for some time together, the air forming a
sort of web or sphere round it that prevents its imme-
diate diffusion and dissipation; and by its contiguity and
exhausted fustian and feeds the fire of the *flame*; the
aqueous and earthy parts of the fume being naturally in-
capable of being ignited, are only rarefied, and so im-
pelled upwards in a dirty cloud without flaming.

Flame is defined by Sir Isaac Newton in his little piece
De Acide, to be *temerarius, red-hot smoke*. But Dr.
Priestley has properly observed, that the smoke of com-
mon fuel consists of two very different things: that which
rises first is rare water, loaded with some of the grosser
parts of the fuel, and is hardly more capable of becoming
red-hot than water itself; but the other kind of smoke
which alone is capable of ignition, is properly *flammabile*
air, which is also loaded with other heterogeneous
matter, so as to appear like a very dense smoke. A
lighted candle shows them to be essentially different;
for one of them instantly takes fire, whereas the other
extinguishes a candle. Priestley on Air, vol. I. p. 207.

Flame may be considered as vapour composed of inflam-
mable parts, and kindled by contact with an ignited
body; by which means, together with the access of air
or vitriol acids, it may be made to undergo those effects
which are produced upon all bodies during their combus-
tion, viz. the decomposition of its parts, the dissipa-
tion of its phlogiston, and the emission of light and heat.
Moreover, it is not merely the vapour of an inflammable
body, but the body itself, that may, by contact with an
ignited body, or by any other mode of exciting heat, as
friction, &c. together with access of air or vitriol acid,
constitute a *flame*, which consists of particles flying off
from that body in the act of combustion. Thus, by applying a
hot iron to sulphur, we may see a *flame* immediately pro-
duced upon the surface of the sulphur; and bodies thus
kindled can only *burn* at their surfaces, because there
only they are contiguous to the air, whereas, when pure
is intimately mixed with the inflammable substance, as in
gunpowder, the whole substance is instantly inflamed,
because the vitriol acid has, like *air*, the property of
maintaining combustion. See *Nature* *Air*. Hence
we may also conceive why the external surface of a *flame*,
by being contiguous to air, is much hotter than its in-
ternal parts, which may be easily evinced by applying
any substance, alterable by heat, alternately to the ex-
terior and interior parts of the *flame* of a candle; and
when a vapour of a foot or eighteen inches diameter is
kindled, and the combustion maintained only by the air
contiguous to it, the *flame* will then be only an inch or
two thick, while the vapour near the centre, surrounded
by the *flame*, is not inflamed. See the remarks of the
ingenious translator of the Chemical Dict. *Art. Flame*.
Sir Isaac Newton, to whose reasoning we return after this
digression, argues, Is not *flame* a vapour, fume, or
exhalation heated red-hot; that is, so hot as to flame?
For bodies do not *burn* without emitting a copious fume;
and this fume burns in the *flame*. The ignis fatuus is a
vapour flaming without heat; and is there not the same
difference between this vapour and *flame* as between
rotten wood flaming without heat, and burning coals
of fire? In distilling hot spirits if the head of the still be
taken off, the vapour which already will take fire at the
flame of a candle, and run into *flame*. Some bodies,
heated by motion or fermentation, if the heat grow in-
tense, flame copiously; and if the heat be great enough,
the fumes will flame, and become *flame*. Metals in-
flamed do not *burn*, for want of a copious fume. All
flaming bodies, as oil, tallow, wax, wood, fossil coal,
pitch, sulphur, &c. by burning, write in *flame*, which
at first is lucid; but at a little distance from the body
ceases to be so, and only continues hot. When the
flame is put out, the smoke is thick, and frequently
fumes

Intells strongly: but in the *flame* it loses its smell; and, according to the nature of the fuel, the *flame* is of different colours. That of sulphur, e. g. is blue; that of copper opened with sulphuric acid, green; that of tallow, yellow; of camphor, white, &c.

From this difference of the colours of the *flames* proceeds the difference of the colours of bodies as viewed by day-light, candle-light, or any one of these *flames*; and for making curious experiments of this kind, oil may be impregnated with copper, &c.

We find that when gun-powder takes fire, it goes off in a *flaming* smoke. The manner we conceive to be this: the charcoal and sulphur easily take fire, and set fire to the nitre; by which the spirit of the nitre being raised into vapour, rather than the vapour of water out of an aqueous. Then the acid spirit of the sulphur entering violently into the fixed body of the nitre, sets loose the spirit of the nitre, and excites a greater fermentation, whereby the heat is increased, and the fixed body of the nitre is raised into flame, and thus is a vehement explosion effected. The *flame* of gun powder arises from a violent action, whereby the mixt being quickly and violently heated, is rarefied and converted into flame and vapour, which vapour, by the violence of the action becoming too hot as to shine, appears in the form of *flame*. Newt. Optics, p. 318. See AIR, FIRE, HEAT, and PHOSPHORUS. It is a remarkable phenomenon of the *flame* of a candle, torch, or the like, that in the dark it appears bigger at a distance than near at hand. The reason is, that at a distance, e. g. of six feet, the eye can readily distinguish between the *flame* and the contiguous air illuminated by it, and sees precisely where the *flame* terminates; but at the distance, e. g. of thirty feet, though the angle subtended by the *flame* be much smaller than before, yet the eye, not being able to distinguish the precise bound of the *flame*, takes part of the sphere of air illuminated by it for the *flame* itself.

We have several instances of actual *flame* being produced by the mixture of two cold fluids. Dr Stern gives us a list of the oils which burn into *flame* upon mixing them with compound spirit of nitre, such are those of caraway, cloves, fennel, gualacum, box, camphor, pepper, hartshorn, blood, &c. Philosoph. Trans. N. 273.

It is evident to every curious observer, that *flame* dwells and plays only about the surface of fuel, having nothing to do with its interior parts. If a lamp-glass be filled with spirit of wine, another with oil of turpentine, and others with other liquors, and each for an fire, it will be easily distinguishable through the sides of the glass, that they all burn and *flame* only on their surface, the *flame* continually rising lower and lower in the glasses as the liquors consume. The same observation holds good in solid as well as liquid fuel, and appears to be universal; and hence we are directed to the choice of proper fuel on the different occasions we want it for. Shaw's Lect. p. 33.

It is observed by Neumann, that the face viewed by the *flame* of wine looks like that of a dead corpse; the *flame* of phosphorus, and of spirit of wine impregnated with fossils, exhibit the same phenomenon. For the effect of joining the *flame* of two candles, see CANDLES. For an account of the generation and extinction of *flame*, according to the theory of Dr Crawford, see HEAT of inflammable, &c. bodies.

FLAME from cold liquids. See FIRE.

FLAME-hot, the flame with white heat. See IRON.

FLAME, verb, FLAMMA, or FLAMMULA, *trans.* a fire, warm, igneous substance, supposed by many both of the ancients and moderns to reside in the hearts of animals, as necessary to life, or rather as that which coagulates life itself.

To the preservation of this *flame*, they suppose air as necessary as it is to the preservation of common *flame*; and hence they ascribe the necessity of respiration to animal life.

Mr. Boyle, by experiments in an exhausted receiver, found, that the vital *flame* of animals, if life may be so called, survives or outlasts the *flame* of spirit of wine, or of a wax or tallow candle, &c. Some animals would remain alive and well in water for three or four minutes, whereas no common *flame* would last there one minute. The light of the glow-worms, he found, would presently be destroyed by exhausting the air, and retrieved again upon its re-admission. Dr Quincy could find nothing more in the notion of vital *flame* than the natural warmth, which is the effect of a circulating blood, and which is always at its velocity. See animal HEAT.

FLAMEN, among the ancient Romans, was a priest or minister of sacrifices.

There were at many kinds of *flames* at Rome as there were gods who had priests and sacrifices offered them.

Vol. II. N. 132.

Romulus and Numa, at first, only instituted three: one for Jupiter, called *flamen Dialis*; another for Mars, called *flamen Martialis*; and a third for Romulus or Quirinus, called *flamen Quirinalis*. Plutarch and Dionysius Halicarnassensis maintain, that Numa created only the last in honour of Romulus; but Livy assures us, that Romulus had instituted only the first, and that the two others were added by Numa; and Varro speaks in the plural number of the *flamines* instituted by Numa. In afterwards twelve more were added, which made the number of *flamines* fifteen.

The three first were taken from among the patricians, and were held of a rank and distinction superior to the rest. They were called *greater flamines*, *flamines maiores*, in contradistinction to the other twelve, who were chosen from among the plebeians, and were therefore called *lesser flamines*, *flamines minores*. The *flamen Dialis*, or of Jupiter, was the first instituted, and held in the greatest esteem. He bore a peculiar ornament on his head, called *alabastrum*, which was made of the skin of a white victim sacrificed to Jupiter.

One of their priests revived an ancient pretension to a seat in the Senate in right of his office, which, by the indulgence of his predecessors, had not been claimed or enjoyed for many generations. The senator rejected his claim, nor would suffer him to sit in that assembly; but upon his appeal to the tribunes of the people, that is, to the people, his right was confirmed, and he was allowed to take his place of a senator. Liv. xxviii. 8. Midclat. of Rom. Sen. p. 49.

The cap worn by the first was called *flamma et apex*. It was made of a sheep's skin, with the wool on, to which was affixed a little branch of an olive tree. That of the *flamen* of Jupiter ended in a point called *uracula*. It was tied under the chin with thine; but in the summer-time it was only a woollen thread tied round the head, it being prohibited them ever to appear quite bare-headed. And hence, according to Festus, came their designation of *flamen*, viz. from *flamma* or *flam*, *flam*.

Though the *flamines* bore one common appellation, yet did they not constitute any company or college. Each god had his several facilities, localities, and ceremonies apart; nor had one *flamen* any relation to another, only they were all subordinate to the pontifex maximus. Aulus Gellius assures us, that they were created by the people in the comitia curiæ; but the pontifex maximus afterwards consecrated them. Their priesthood, called *flaminatus*, was perpetual, though on some occasions they might be deposed.

The names of the several *flamines* are as follow: the three great *flamines*, as already observed, were the *flamen Dialis*, *flamen Martialis*, and *flamen Quirinalis*; the twelve lesser were the *flamen Comestialis*, or priest of the goddess Ceres; mentioned by Cicero in his Brutus; *flamen Palatialis*, or priest of the god Palaces, a name whose origin, Varro observes, is not known; *flamen Lavinialis*, or of the goddess Lavinia; *flamen Feronianus*, whose etymology is not known; *flamen Lucretialis*, *flamen Lucerinus*, *flamen Palatialis*, whose some moderns will have to be the priest of the goddess that presided over the palatium, though Varro owns himself at a loss for it originally; *flamen Potentialis*, or of Potomus, goddess of fruits; *flamen Vestivialis*, or of the god Vestib, whom some take for the same with Hippocritus; *flamen Volturnalis*, or of Vulcan; and *flamen Volturnalis*, or of the god Volturnus. Some authors also speak of the *flamen Hecateus*, priest of Hecate; *flamen Jovis Capensis*, of Julius Caesar; and *flamen Agrippalis*; and Commodus likewise had a *flamen* created under the title of *flamen Heracleus Commodianus*.

They had also their *flamine* or *flaminæ*, who were wives of the *flamines*, or the priestesses of the deity. In an ancient marble, quoted by Gruter, p. cccciii. n. 6. the word *flaminia* is used for priestess; and in the same author, p. ccccviii. n. 7. the priestess of the goddess Feronia is called *FLAMINIA FERONIA*, that is *flamina*, or *flaminia Feronia*. The *flamine* bore the same ornament on her head with the *flamen*. She had also the same surname of silence with her husband, as *flamina Dialis*, *Martialis*, &c.

FLAMETTE, in Libbylogy, a name given by the French writers to a species of charms or shell-fish of the bivalve kind, with its shell always more or less open: this species is as hot as pepper to the taste.

FLAMINGO, in Ornithology, the name of a very beautiful and very remarkable bird; it has long legs, and a long neck; yet has webbed feet, and is remarkable for the fine bright red of its wings.

Its beak is broad and of a very singular figure; the upper chap being bent, depressed, and dented; the lower, much thicker and firmer. It is black at the end, and in the other part of a dusky blue. Its neck and body are white; the long flight feathers of its wings black; but

but the shorter feathers, which make the covering of the wings, are of a very elegant and bright red, whence the bird has its name. It lives about waters, and feeds on fish. It is common in many parts of America, and is seen at times in many parts of Europe. It is well known to the ancients, and its tongue was accounted a very great delicacy among the nice eaters of old times. See *Tab. II. of Birds, N. 10.*

One thing very remarkable about it, that its beak is so long and crooked, that the whole head must be immersed before the water can get into it. See a learned and elaborate History of this bird in the Phil. Trans. Act. vol. x. p. 51. &c.

FLAMMA *Troia*, a name given by many writers to a plant of the *Samolus* or *Vivipar* kind called by the Greeks *whortlewood*.

FLAMMULA, or *FLAMULEA*, under the *Egyptian Empire*, was a kind of flag terminating in a point somewhat like a dome, bearing as a mark or badge to distinguish the followers of the several companies, battalions, regiments, &c. In Greek it was called *ganaxia*; it was sometimes placed on the calque, sometimes on the cuirass, and sometimes at the end or tip of the pike, &c.

The emperor Maurice ordered, that the *flamula* of each division should be of a particular colour, to distinguish them from the other battalions or brigades. They used to lay aside the *flamula* before an engagement, lest it should prove an impediment. The cavalry had also *flamula* on their helmets, to distinguish the troops they belonged to.

FLAMMULA, in *Brassica*, a name given by some authors to a particular species of the crucifera, commonly called the *rammucata brassica*.

FLAMULEA *auri*, in *Natural History*, a name given by Dr. Woodward, and others, to those small pieces of gold found among the veins of silver in some places. They are sometimes found in roundish pieces, but more usually in their shining fibres, whence the name *flamulea* seems to have been given them, as being very bright and glossy. This sort of gold is pure and malleable, and loses scarce any part of its weight in fusion.

The gold dust, as it is called, which is brought from Guinea is much of this kind; its particles are usually very small, though sometimes lumps of the size of a pea or horse bean are found, and sometimes masses of an irregular figure of three or four ounces weight; but their softness the name of *flamula* when they become to thick and solid, and to large, and are called by the merchants rock-gold. Woodward Cat. Foss. vol. ii. p. 33. See *GOLD*.

FLANCH, *FLANQUE*, or *FLANQUEE*, an ordinary in *Heraldry*, formed by an archeline, which begins at the corners of the chief, and ends at the base of the escutcheon.

He beareth ermin two *flanches* vert. See *Tab. Herald. N. 15.* *Flanches* are always borne by pairs.

Lothi make's *flanche* and *foxt* two distinct hearings, whereas the former is more bent than the latter; but Gibbon judiciously makes them but one, which he calls *flanche*.

FLANCONADE, in *Fencing*, is the action of dropping the point of your sword under your adversary's hit, in seizing with force the feeble of his blade; which, binding without giving him, form the parry in epee, and then throw in your thrust.

FLANEL, or *FLANNET*, a kind of light, loose, woollen stuff, not quilted, but very warm, composed of a velvet and warp, and made on a loom with two shuttles, after the manner of *BAYS*.

It has been observed that new *flanel*, after some time wearing, acquires the property of floating in the lake, but loses it on being washed. Philof. Trans. N. 433. 67. See *FLUORETIV*.

FLANK, or *FLANK*, in the *Manoeuvres*, is applied to the sides of a fort's batteries, &c.

In a *flank* sense the *flanks* of a terrace are the extremes of the belly, where the ribs are wanting, and are below the loins.

The *flanks* of a horse should be full, and at the top of each a feather. The distance between the last rib and haunch bone, which is properly the *flank*, should be short, which they term *well shaped*, such horses being much better, and fit to endure labour.

A horse is said to have no *flank* if the last of the ribs lies at a considerable distance from the haunch-bone, as also when the ribs are too much freighted in their compass.

FLANK, in *War*, is used by way of analogy for the side of a battalion, army, &c. in contradistinction to the *front* and *rear*.

To *flank the enemy in flank*, is to discover and fire upon them on one side. See *FLANK*.

FLANK, in *Fortification*, is a line drawn from the extremity of the face toward the inside of the work. Such is the line BA, *Tab. Fortification, fig. 1.* and EF and JN, *fig. 16.*

Or *flank* is that part of a bastion which reaches from the curtain to the face, and defends the opposite face, the *flank*, and the curtain.

FLANK, *align* or *flank*, is that part of the curtain, EI, intercepted between the greater line of defence, EC, and the lesser, IC, and from which they can see to scour the face of the opposite bastion.

FLANK, *long*, *short*, or *raised*, is the platform of the casement which lies hid in the bastion; otherwise called the *GRILLON*.

FLANK *flanch* is that from whence a cannon plays, forth bullets directly to the face of the opposite bastion.

FLANK *rearm*, or *rearm*, is the point from whence the line of defence begins, from the conjunction of which with the curtain, the first entry is called the face of the next bastion, which happens when the face cannot be discovered but from that point alone.

FLANKS, *Angles*, are lines going from the angle of the shoulder to the curtain, whose chief office is for defence of the most and place.

FLANKED, *FLANQUEE*, is used by the French heralds to express our party per pale, that is, when the field is divided into four parts, after the manner of an X. Though Columbiere uses the term in another sense, which appears more natural, viz. for the taking of flanches, or running sections out of the sides of the escutcheons; the full from the angles of it, the latter in straight lines, forming an angle at the feet, without making any falter.

FLANKED *angle*, in *Fortification*, is the angle formed by the two faces of the bastion, and which of course forms the point of the bastion.

FLANKED *line of defence*, in *Fortification*. See *ANGLE* and *LINE OF DEFENCE*.

FLANKED *tenail*, is called also *TENAILLE*.

FLANKING, in the general, is the art of discovering and firing upon the side of a place, body, battalion, &c.

To *flank* a place, is to displace a place or other work in such a manner as that there shall be no part of the place but what may be played on, both in front and rear.

Any fortification that has no defence but full right forwards is faulty, and to render it complete, one part ought to be made to flank the other. Hence the curtain is always the strongest part of any place, because it is flanked at each end.

Battalions also are said to be *flanked* by the wings of the cavalry. A house is sometimes said to be *flanked* with two pavilions, or two galleries, meaning it has a gallery, &c. on each side.

FLANKING *angle*. See *ANGLE*.

FLANKING *part of defence*. See *LINE OF DEFENCE*.

FLASK, in the *Artillery*. See *POWDER FLASK*.

FLASK, *FLASQUE*, a bearing more properly called *flanche* or *FLANCHE*.

FLAT, in *Sea-language*, denotes a level ground lying at a small depth under the surface of the sea, and is also called a *thal* or *thalow*.

FLAT *logins*, in *Fortification*. See *BATTION*.

FLAT *Artillery* *guns* are such as are made to swim in shallow water, and to carry a great number of troops, artillery, ammunition, &c. They are constructed with a twelve-pounder, bow-chafe, and an eighteen pounder, item-chafe; their keel is from sixty to one hundred feet, and from twelve to twenty-four feet beam: they have one mast, a large square main-sail, and a jib-sail, are rowed by eighteen or twenty oars, and can carry four hundred men each.

The gun takes up one bow, and a bridge the other, over which the troops are to march. Those that carry horses have the fore-part of the boat made to open when the men are to mount and ride over a bridge.

FLAT *Artillery*, in *Fortification*. See *BATTION*.

FLAT *Artillery*, in *Fortification*. See *BATTION*.

FLAYING, in *Sea-language*, is to draw in the almost lower corner or clew of a sail towards the middle of the ship, to give the sail a greater power of tacking the vessel. Thus, if the mizzen or after-sails are *flayed*, this action is intended to carry the stern to leeward, and turn the head round to the direction of the wind; and if the head-sails are *flayed*, the intention is to make the ship fall off, when by accident, or design, she has come to near the wind so to make the sail loose.

To *FLAY* *in forward*, is to draw in the fore-sheets, jib-sheet, and fore-lay-fall-sheet toward the middle of the ship. This operation is seldom performed except in light breezes of wind, when the helm has not sufficient government of the ship.

FLATS, in *Music*, a kind of additional or half notes, contrived

joined together with sharps, to remedy the defects of musical instruments.

The natural scale of music being limited to fixed sounds, and adjusted to an instrument, the instrument will be found defective in several points; as particularly, in that we can only proceed from any note by one particular order of degrees; for that for this reason we cannot find any interval required from any note or letter upwards or downwards; and that a long may be so contrived, as that if it be begun by any particular note or letter, all the intervals or other notes shall be justly found on the instrument, or in the fixed series; yet were the long begun with any other note, we could not proceed.

To remove or supply this defect, musicians have recourse to a false proceeding by twelve degrees; that is, thirteen notes, including the extremes, to an octave, which makes the instrument perfect, that there is but little to complain of. This, therefore, is the present system of the scale for instruments, viz. between the extremes of every note of the natural scale is put a note, which divides it into two unequal parts, called *semitones*; and the whole may be called the *semitone scale*, containing twelve semitones betwixt thirteen notes in the compass of the octave.

Now, to preserve the diatonic series distinct, these inserted notes either take the name of the natural note next below with a character, called a *sharp*; or they take the name of the natural note next above with a mark called *flat*. Thus *D flat* signifies a semitone below the D natural; and it is indifferent, in the main, whether the inserted note be accented as a *flat* or a *sharp*.

The semitone series of scale is very exactly represented by the keys of a spinnet; the fermest range or keys being the natural notes, and keys behind, the artificial notes, or the *flat* and *sharp*.

FLAT-third, in *Music*, the third minor. See INTERVAL. **FLATTER**, or **FLATTENING**. See COINING.

FLATTING, or **FLATTENING**. See COINING.

FLATTING-out, among *Brass-makers*. See BRICK.

FLATTING-mill. See MILL and GOLD-WIRE.

FLATULENCY, a word used by medical writers to express a distended state of the body, in which there is an uncommon and unnatural generation of flatus or flatus and elastic matter of the nature of air, arising from the humidity of the abdomen, and attended with several very bad symptoms.

Some authors mention flatulency of the uterus and of the bladder; but these are very rare cases, though they do sometimes happen; and what is usually understood by the word *flatulency*, are such flatulencies in the stomach and bowels. These are either torpid or impetuous.

The torpid flatulency of the bowels gives the patient very little uneasiness; people of phlegmatic habits are much subject to them, and generally very little regard them. But the impetuous kind very often occasions the utmost disorder, on the slightest accidental occasion irritating them; people of a sanguine and melancholic habit are most subject to them. *Flatulencies* differ also greatly in regard to their causes, for some are only occasioned by a simple languor or small loss of tone in the intestines, in which case the flatulencies are generally discharged upwards in eructations or downwards, without trouble. Other *flatulencies* have their origin from a tough viscid matter, which destroys the intent of the peristaltic motion in this passage; and in this case the patient is sometimes troubled with spastic contractions of the intestines, sometimes with troublesome relaxations of them; and finally some *flatulencies* take their origin from a turbulent commotion of the blood about the vena porta, from the ramifications of this vessel having connections with the intestines.

Signs of flatulency. The most obvious of these are the rumblings that are felt in the bowels, with noises in them; and in the place of these rumblings, there are sometimes plainly perceived fixed distensions of them in particular parts, with tension and firmness of the abdomen. From the continuance of these symptoms arise pains which sometimes change place, and sometimes remain fixed, and seem to swell the intestines in such manner as to enlarge building; and when commotions of the blood are the cause of these, there are usually pains felt attending them on the left side, and about the region of the heart, and the patient complains of the usual symptoms of hypochondriacal people.

An obstinate colic is also usually attended this distension, which always makes it more violent; and a flatulency of the bowels, attended with anxieties and difficulties of breathing, are usually the attendant symptoms on it, when violent. The more the flatulency has been owing to eructations in the prime viæ, the more will the patient be affected with vertiginous complaints, and other disorders of the head; and when the cause is a commotion of blood about the vena porta, the pains are always

very violent, and are often attended with bad consequences.

Persons subject to it. *Flatulency* attacks persons of all ages, sexes, and constitutions, but especially the phlegmatic, whose parts are of a weaker tone, and naturally more subject to expansion; after these, persons of a sanguine habit are most subject to them, and those of choleric and melancholic habits, though naturally less subject to them, yet often fall into them after illness.

People who are particularly sensible of the changes of the air from warmer to colder, are also more subject to them than those of a more robust and less delicate frame; hence women are more subject to them than men, and those especially in the times of the menses and lochia.

Causes of them. These are in general a relaxation of the peristaltic motion of the guts; but this not extending to the whole canal, but only to some one part, the translocation of the salutary matter being chiefly into this flaccid part, which it distends in a manner that it could not do by any part that had its natural tone and motions. And the defect in one part is always attended with the excess of the peristaltic motion in another, in order to the driving off the excreta; hence proceed alternate contractions and relaxations, to which, in a great measure, the pain is owing; and in cases of the commotions of the blood about the vena porta, the same contractions and relaxations always happen. The material causes of *flatulency*, are those substances swallowed in food, which are of a mucous and tenacious consistence, and by their obstinately adhering to the bowels are capable of giving great trouble. Of this kind are the herbs in use in food, which are of a thick tough juice; or the leguminous tribe, as peas, beans, and the like; also dried sea-fish, and all animal fat, as that of sheep and calves, especially if the person drink immediately after eating heartily of them. The drinking of saculent liquors will also occasion them very violently, as new malt liquor, or the same when the vessels are small out the summer-fruits are also chargeable with these effects, and above all things honey. To all these causes, the habit of the patient greatly concurs, and a general coolness of the body, and dryness of the bowels, are a frequent occasion of them.

Prognosis in them. *Flatulency* often prove an extremely troublesome complaint, and people of an idle sedentary life, especially women, owe a great many uneasy hours to them; and when they grow into a habit, they are always attended with colic pains, cardialgia, anxieties, and fustatory emotions: it is always to be observed, that the forcible suppression of flatulency, brings on much worse complaint, especially in puerperæ and sanguine habits; for spastic twinnings of the bowels, and vibratile convulsions, with faintings, are often the consequences of it; and the physician is apt to scarce fortuitous or fortuitous habits of the blood, for the symptoms he discovers, which, in such, are only owing to such a suppression. The free discharging of *flatulency*, on the other hand, is attended with its ill consequence, because it naturally degenerates into a habit.

The suppression of habitual *flatulency* brings on tumors, indurations of the abdomen, hiccups, and a tympanites, and particularly the anterior flatulency; these, which might be avoided by eructations, when suppressed, bring on cardialgia and vertiginous disorders of the head. **Method of cure**. In this it is first to be considered, whether the flatulency have their origin in the bowels, or whether they affect them only by content, as is often the case in distases of the neighbouring parts in hypochondriac and hysterical patients, and in persons afflicted with hæmorrhoidal and nephritic complaints, and in cases where women have been ill managed in lying-in, or in miscarriages: in all these cases, the original cause is to be considered and treated with its proper remedies. But in cases of direct and simple *flatulency*, the following method will be usually found effectual. The bowels must be carefully kept gently open; for in cases of colic, *flatulency* will always be increased. To this purpose, the common cathartics must be given at repeated times, and to these, by way of increasing the stimulus, some of the lesser cathartics is to be added, and some common salt. After these the laxative medicines of the peder kind are to be given, and in the intermediate days, the digestive salts, to attenuate the viscid matter in the bowels; to these urine and a little cinabar may be added, and these always have a much better effect than all the hæmorrhagics usually given. After these, the things are to be given which relieve the tone of the parts, such as the bitter and aromatic extracts, with spirit of salt of tartar, spirit of nitre dulcified, and the volatile acridous salts aromatised. Externally, some of the plasters may be applied to the pit of the stomach, as may also the rhubarb balsam, such as the oils of nutmeg, card, fennel, and the like.

The general method of treating *flatulencies*, is by the hot aromatics; but these are to be given with great caution; for when the commotions of the blood about the *vena porta* are in fault, these things always irritate rather than do good; but beyond all things, the too common method of giving a vomit in these cases is to be avoided; for the discharge of the *flatulencies* upwards is inverted by this means, and then usually follow caputic pains and tensions of the parts, difficulty of breathing and vertiginous complaints in the head, with noises in the ears, and many other complaints, which are continually increasing, till they are a little eased for the present by an eructation. The happy way of getting rid of these anterior flatulencies, is by driving the cause of them downwards, and restoring the lost tone of the parts. Continued exercise is also of the utmost service. *Junken's Consil. Med. p. 600.*

Dr. Whytt recommends water and laudanum as the most effectual medicines for expelling wind. He generally gave the laudanum in a mixture with pepper-mint water and tincture of castor, or sweet spirits of nitre: and sometimes opium in pills, with assa-tida. The dose of either is a tea-spoonful mixed with two table-spoonfuls of water. He also in some cases advises external applications; as equal parts of the anodyne and stomachic plaster, spread on a piece of soft leather, of such size as to cover a great part of the belly; and a table-spoonful of the following ingredients mixed together, and well rubbed on the parts at bed-time; viz. Bala's anodyne balsam, an ounce; the extracted oil of mace, half an ounce; and two drams of oil of mint. For strengthening the stomach and bowels, and lessening the production of *flatulency*, he recommends the Peruvian bark, butters, chalybeats, and exercise. To remove the colicivents, which often attend windy complaints, four or five of the following pills should be taken every night at bed-time: take of assa-tida, two drams; Socotrine aloes, salt of iron, and powdered ginger, of each one dram; and as much of the elixir proprietatis as will be sufficient to form them into pills. When the body is too open, twelve or fifteen grains of rhubarb, with half a dram, or two scruples, of the Japonic confection, may be taken every other evening with advantage. *Flatulencies* that attend the cessation of the menses are relieved by repeated small bleedings. With regard to diet, tea and all stercorantia should be avoided; and as for drink, water, with a little brandy or rum, is not only preferable to multum, but, in most cases, is wisest.

FLATULENT, something that has a relation to flatulency, or blasts of wind.

Peas, and most kind of pulse, onions, &c. are *flatulent foods*.

FLAUTINO, in the *Italian Music*, the name of a small flute or *FLAGEOLET*.

FLAUTO, in the *Italian Music*, is used to denote a flute, or the part to be played by that instrument.

FLAUTO, *transfers*, in the *Italian Music*, a German flute.

FLAW, at Sea, signifies a sudden gust of wind, otherwise called *squall*.

FLAX, *Linum*, in *Botany*, a genus of the *pentandria pentagyna* class. Its characters are these: the flower has a permanent empalement, composed of five small four-shaped sear leaves; and five large oblong petals, which spread open; and five awl-shaped erect stamens, terminated by arrow-shaped summits. In the centre is situated an oval germ, supporting five slender styles, crowned by reflex stigmas, and afterwards turns to a globular capsule with ten cells, opening with five valves; in each cell is lodged one oval, plain, smooth seed, with an acute point. There are fourteen species. Miller.

The common flax is an annual plant that will grow in any kind of good found land, but that does best for it, which has lain some time unploughed. The best land yields the best flax, and makes the greatest improvement; and upon the whole, it is an excellent commodity, and the sowing and ordering it is so good a piece of husbandry, that it well deserves to be more frequently practised among us. It is a plant that exhausts the land very much; on which account it is best to sow it on very rich ground, and not two years together on the same piece. If the land is situated in a valley, or the soil has been thrown up by rivers, or if there be water at a small depth below the surface, it is thought better. To this last circumstance it is owing, that Zealand is remarkable for the fineness of its flax, and that the other provinces of Holland do not succeed so well in the culture of this plant. However, Mr. Dandaniel observes, that strong land can hardly yield fine flax, as that which grows on lighter grounds; though a moist stiff soil yields larger quantities, and better seed. The time of sowing is in the latter end of March, when the weather is mild and

warm; the land should be well prepared, cleared from weeds, and laid even; and the strictest caution that can be should be chosen for the sowing it. The ground should be followed two winters and one summer; and between each ploughing it should be well harrowed, in order to destroy the weeds, and pulverize the soil. The dung should not be laid on till the last ploughing, when it must be buried in the ground, and care should be taken that the dung be free from weeds. The Livings, when they clear wood land, burn the wood upon it, and then plough it, and in this state prefer it to any other soil for flax. The best way of sowing flax, is to drill it in equidistant rows, about ten inches from one another. When the flax is thus sown, the ground may be easily broken, to destroy the weeds, which, repeated twice in dry weather, will keep the ground clean till the flax is ripe. Some have recommended feeding the sheep with flax, when it is risen to a good height; but Mr. Miller condemns this as a wrong practice; because, if the sheep gnaw the flax, the plants will flower up very weak, and never come to half the size they would have done, if not cropped. Flax is sometimes damaged by insects, when it is about three or four inches high; it has been said that they may be destroyed by a slight throwing of foot, ashes, &c. This dressing will, at least, give vigour to the flax, though it should not kill the insects.

Two or three bushels of good seed, sown in broad-cast, are required for an acre; but half the quantity in drills will produce a greater crop. The thicker the seed is sown, the finer thread will the flax produce, but the seed will be of an inferior quality. Towards the latter end of August the flax will begin to ripen, but it must not stand till too ripe, but must be pulled as soon as the seed grows brown, and bends down the head.

The best seed is that brought from the east country, particularly from Russia, whence great quantities are imported into Scotland and Ireland, to the amount of many thousand pounds sterling per annum. The best seed is short, roundish, firm, oily, heavy, and of a shining or clear brown colour; which, though dark, repays the charges with abundance.

Flax, pulled up in the bloom, proves whiter and stronger, than if left standing till the seed is ripe; but then the seed is lost. However, the thread will be stronger when the flax is left till the seed is ripe, provided it is not left to stand too long, but the colour of it will not be so good. In Holland, when the flax is pulled, it is laid in handfuls on the ground, with the heads towards the south, and thus piled in heaps, when the weather is uncertain; but in dry weather it is spread in handfuls on the field, and left for twelve or fourteen days to dry. However, this drying is not necessary for the spinning; and therefore, in some parts of Britain, they ripen the flax after it has been in the air two or three days; and even one day will be sufficient, if the weather be dry.

The Siberian perennial flax *sowers* very well for making common strong linen; but the thread spun from this is not so fine or white as that produced from the common sort; but the roots of this kind of flax will continue many years, so that there will be a great saving of culture, as it will require no other care, besides keeping it constantly clean from weeds. The flax seed is most liable to be laid in stormy weather; to guard against this accident, some persons run across their flax fields border poles fixed to stakes; but a better method is to run small ropes across the field, both lengthwise and breadthwise; for these, being fastened where they intersect one another, and supported by stakes at due distances, form a kind of netting, which is proof against almost any accident that can happen from tempestuous weather.

For the preparations flax must undergo, to fit it for spinning, as pulling, drying, and bringing, see *FLAX*. They have a very good way of beating their hemp and flax in Derbyshire, which is that they make the size-tree of the main wheel of their corn mills longer than ordinary, and place pint in it to raise large hammers, like those used in the paper and fulling-mills; and with these they beat the flax, and save a great deal of labour. See *FLAX*.

In the Swedish Transactions for 1737, we have the following method of preparing flax to be spun in Scotland, in which the flax is as well as in Scotland. For this purpose, a little flax-water is directed to be put into an iron pot, or an untinned copper kettle, and a mixture of equal parts of linseed-oil, and quick-lime strewn upon it. A small bundle of flax is to be opened and spread upon the surface, and covered with more of the mixture, and the flax are to be continued till the vessel is sufficiently filled. The whole is then to be boiled with less-water for ten hours; fresh water being occasionally supplied in proportion to the expansion, that the matter may never become dry. The boiled flax

is to be immediately washed in the sea, by a little at a time, in a bucket, with a smooth stick; when it is become cold enough to be borne by the hands, it must be well rubbed, washed with soap, and laid to bleach, and turned and watered every day. Repetitions of washing with the soap, expedite the bleaching; after which the *flax* is to be beat, and again well washed. When dry, it is to be worked and carded in the same manner as common cotton, and pressed betwixt two boards for forty-eight hours. It is now fully prepared, and fit for use. It loses in this process near one half of its weight, which is abundantly compensated by the improvement made in its quality.

Flax has one quality not taken notice of by botanical writers, which is, that the herb, infused in water, as in ponds or rivers, as is practised, in order to rot the stem, and procure the bark for mechanical purposes, communicates the water a very poisonous quality; inasmuch that cattle which drink it die, and the fish in such waters are poisoned; it is therefore forbid to be watered in any running stream, or common pond, by 21 Hen. VIII. cap. 17. This plant yields, by means of a retort, a greatly valuable, resembling oil of mace, and called by some butter of *flax*.

The seed, which is usually called *linseed*, is emollient, digesting, and ripening; of great use against inflammations, tumors, and impostumes; and is frequently put into fomentations and cataplasms for those purposes. Cold drawn linseed oil is of great service in all diseases of the breast and lungs; as peripneumonies, pleuritis, coughs, asthma, contumptions, colics, and constipations of the belly. It likewise helps the colic and flue, both when taken by the mouth, and given in clysters. The oil by expression is the only official preparation.

This oil, when carefully drawn, without the application of heat, has no particular taste or flavour, though in some properties it differs considerably from most of the other oils of this kind; not congealing in winter; not forming a solid soap with fixed alkaline salts; and acting more powerfully, as a menstruum, on subterraneous bodies, than any other expressed oil that has been tried. It is also supposed to be of a more healing and balsamic nature than the other oils of this class. Lewis, Mat. Med. In pleuritic pains, says Ruysers, Ephem. Germ. An. 6 & 7. he has often experienced linseed oil to be the most successful medicine he could prescribe; for it immediately facilitated respiration, and promoted spitting. In a hæmoptoe also, he exhibited the same oil with the desired success; for by its balsamic and emplastic virtue it consolidates the affected parts.

Linseed oil is of such subtle parts, as not to be kept in earthen vessels without stratification. Meyerus de Luso Isio. Tumors of the belly are very happily cured by the use of linseed oil. Ephem. Germ. An. 3.

FLAX, *Caribæa*. See POLYPERMUM.

FLAX, *purging*. See LINUM catharticum.

FLAX, *reed*, *Linaria*, in History. Its characters are these:

The flower has a permanent empanement of one leaf, divided into five parts almost at the bottom, and one petal of the ringlet kind, having an oblong swelling tube, with two lips above, and the chaps below. The upper lip is hind and reflected on the sides; the lower lip is trilled and obtuse. It hath an oblong obovatum, and shaped, and prominent behind, and four stamens, which are included in the upper lip, two of which are shorter than the other; and a roundish germen, supporting a single style, crowned by an obtuse stigma, which afterwards turns to a roundish, obtuse capsule, with two cells, filled with small seed. There are seventeen species. Miller.

This is joined by Linnaeus to the *astirrhæum*. See SNAY-DRAGON.

The first species of these plants grows in great plenty on the sides of dry banks in most parts of England. It flowers in July and August, and would make an agreeable appearance in gardens, where it might be allowed a place, were it not for its creeping roots, which spread too much. It is one of the simples, in the catalogue of simples, of the College Dispensatory, to be used in medicine. The leaves have a bitterish, and somewhat saline taste; and when rubbed between the fingers yield a faint smell, resembling that of elder.

The whole herb is used, and is of an aperitive and diuretic nature, opening obstructions of the liver and spleen, relieving the dropsy and jaundice, which it carries off by urine. The ointment made with hog's lard, and a good quantity of this herb, is accounted excellent for the piles, being mixed with the yolk of an egg, and applied to the part. James.

The only official preparation is the *argumentum linariae*.

FLAX, *Bellard reed*. See TURBEM.

FLAX-plant, is a name which we may give to a plant that serves the inhabitants of New Zealand instead of hemp Vol. II. N° 133.

and *flax*. Of this plant there are two sorts; the leaves of both resemble those of flax, but the flowers are smaller, and their clusters more numerous; in one kind they are yellow, and in the other a deep red. Of the leaves of these plants, with very little preparation, they make all their common apparel, and also their strings, lines, and cordage, for every purpose, which are so much stronger than any thing we can make with hemp, that they will not bear a comparison. From the same plant, by another preparation, they draw long slender fibres, which flur like silk, and are as white as snow: of these which are very strong, they make their best cloaths; and of the leaves, without any other preparation than splitting them into proper breadths, and tying the strips together, they make their fishing-nets, some of which are of an enormous size. Hawkesworth's Voyag. vol. III. p. 39.

The seeds of this valuable plant have been brought over into England; but, upon trial, appeared to have lost their vegetating power.

The filamentous parts of different vegetables have been employed in different countries for the same mechanic uses as hemp and flax among us. Puteuchien, and in some degree alkaline fixity, destroy the pulp or fleshy matter, and leave the tough filaments entire. By curiously preserving the rest of a plant in water, we obtain the fine flexible fibres, which constituted the basis of the ribs and minute veins, and which form, as it were, a skeleton of the leaf. In Madagascar, different kinds of cloth are prepared from the filaments of the bark of certain trees, boiled in strong ley; and some of these cloths are very fine, and approach to the fineness of silk, but in durability come short of cotton; others are coarser and stronger and last twice as long as cotton; and of these filaments they make sails and cordage to their vessels.

The stalks of nettles are sometimes used for like purposes even in France; and Sir Hans Sloane relates, in one of his letters to Mr. Ray, that he has been informed by several, that mullein and callico, and most of the Indian linens, are made of nettles. A strong kind of cloth is said to be prepared in some of the provinces of Sweden of pop-stalks; and in the Transactions of the Swedish Academy for 1750, we have an account of an experiment relating to this subject: a quantity of the stalks was gathered in autumn, which was equal in bulk to a quantity of flax sufficient to yield a pound after preparation. The stalks were put into water, and kept covered with it during the winter. In March they were taken out, dried in a stove, and dressed as flax. The prepared filaments weighed nearly a pound, and proved fine, soft, and white; they were spun and wove into cloths of fine strong cloth. Unless the stalks are fully rotted, which will take much longer time than flax, the woody part will not separate, and the cloth will prove neither white nor fine. See Dr. Lewis's notes to Neumann's Chemistry, p. 426, 429.

FLAX, *Pales*, in Natural History, a genus of the aptera class of insects; of a roundish compressed figure, with two eyes, six feet formed for leaping, and sixteen antennae; the mouth is bent downwards, and concealed a small ring or piercer. The generation of this familiar vermin affords something very curious, first discovered by Sig. Dacinto Colonna.

Flax bring forth eggs, or nits, which they deposit on animals that afford them a proper food; these eggs being very round and smooth, usually slip fruit down; unless detained by the piles, or other inequalities, of the cloaths, hairs, &c.

Of these eggs are hatched white worms, of a shining pearl colour, which feed on the fleshy substance of the cuticle, the downy matter gathered in the piles of cloaths, or other like substances.

In a fortnight they come to a tolerable size, and are very lively and active; and, if at any time disturbed, they suddenly roll themselves into a kind of ball.

Soon after this, they come to creep, after the manner of silk-worms, with a very swift motion. When arrived at their size they hide themselves as much as possible, and spin a silken thread out of their mouth, wherewith they form themselves a small round bag, or case, white within as paper, but without always dirty, and fouled with dust. Here, after a fortnight's rest, the animalcule bursts out, transformed into a perfect flax; leaving its exuvie in the bag.

While it remains in the bag it is milk-white, till the second day before its eruption; when it becomes coloured, grows hard, and gets strength; so that, upon its first delivery, it springs nimbly away. Phil. Trans. N° 249. The flax when examined by the microscope affords a very pleasing object. It is covered all over with black, hard and fleshy scales, or plates, which are curiously jointed, and folded one over another in such a manner, as to com-

ply with all the nimble motions of the creature. These scales are all curiously polished, and are beset about the edges with short spikes in a very beautiful and regular order. Its neck is finely arched, and much resembles the tail of a lobster; the head also is very extraordinary; for from the lowest part of it there proceed the two fore-legs, and between these is placed the piercer or sucker, with which it penetrates the skin to get its food.

Its eyes are very large and beautiful, and it has two short horns or feelers. It has four other legs joined all at the breast. These, when it leaps, fold short one within another, and then exerting their spring all at the same instant, they carry the creature to a surprising distance.

The legs have several joints, and are very hairy, and terminate in two long and hooked sharp claws.

The piercer or sucker of the *fla* is lodged between its fore-legs, and includes a couple of darts or lancets, which after the piercer has made an entrance, are thrust farthest into the flesh, to make the blood flow from the adjacent parts, and occasion that red round spot, with a hole in the centre of it, vulgarly called a *fla* hole.

This piercer, in thrust opening sideways, and the two lancets within it, are very difficult to be seen, unless the two fore-legs, between which they are hid, be cut off close to the head; for the *fla* rarely puts out its piercer, except at the time of feeding, but keeps it folded inwardly; and the best way of seeing it is by cutting off first the head, and then the fore-legs, and then it is usually seen thrust out in convulsions.

By keeping fresh in a glass tube corked up at both ends, but so as to admit fresh air, their several actions may be observed, and particularly their way of coupling, which is performed tail to tail; the female, which is much the larger, standing over the male; they may also be thus seen to lay their eggs, not all at once, but ten or twelve in a day for several days successively, which eggs will be afterwards found to hatch successively in the same order. The *fla* may easily be dissected in a drop of water and by this means the stomach and bowels, with their peristaltic motion, may be discovered very plainly, as also their testes and penis, with the veins and arteries, though minute beyond all conception. Mr. Levenhooke affirms also, that he has seen innumerable animalcules flapped like banners, in the frozen mucus of a *fla*. *Baker's Microscop.* p. 191 and 194.

FLA-HUE, in Botany, *Cymus*, a genus of the *hyssopus* polygamia superflua class. Its characters are as follow: it hath a compound flower, made up of many hermaphrodite flowers, which compose the disk, and female half flowers, which form the rays; the hermaphrodite rays are funnel-shaped, and cut into five parts at the limb, and have each five short hairy filamina; in the bottom of each lobe is situated a germ. The female half flowers, or rays, are funnel-shaped, and cut into three parts at the top; these have a germ. The hermaphrodite and female flowers are each succeeded by one oblong seed, crowned with down, sitting upon a plain receptacle, and are included in the envelopment. Miller enumerates seventeen species.

The common *fla-hue* stands recommended by the old authors as a remedy for many cutaneous disorders. They had an opinion also, that the smoke of it when burnt in a room destroyed fleas, and other insects.

FLA-HUE, flinty, African. See **TARCHONANTHUS**.

FLA-HUE, sweet. See **GROUNDHEL**.

FLA-HUE, marsh, Italian. See **ELUCAMPANE**.

FLA-HUE, *Physium*, in Botany, the name of a genus of plants, the flowers and fruit of which are like those of the **PLANTAIN**, to which *Linnaeus* has joined it; but the stalks are ramose and foliaceous.

The seeds of *physium* are recommended by many in jaundices and dysenteries; but the present practice receives it only as a mucilaginous feed.

FLA-HUE colour of a horse is white, spotted all over with dark reddish spots.

FLA-M, a small instrument of pure steel, composed of two or three moveable lancets, for bleeding a horse, or the like.

A case of *flam* as it is called by farriers, comprehends six sorts of instruments; two hook-knives, called *drawers*, and used for cleansing wounds; a penknife, a sharp pointed lance for making incisions; and two flaps, one sharp, and the other broad, pointed; these last are somewhat like the point of a lancet, fixed in a flat handle, only no longer than it is necessary to open the vein.

Flam imported, before the day on foot, pay each ^{12d} ₁₀₀ and drawback on exportation ^{12d} ₁₀₀.

There are many surgeons in Germany who bleed, or perform the operation of phlebotomy with this instrument, which they use in this manner: they hold one finger upon the end of it, which serves as a handle, and applying the point to the vein they are to open, strike upon

the back over the point with one of the fingers of the other hand, opening the vein much as farriers bleed horses. Others use a spring *flam*, something like a single point of the scarifying instrument used in cupping; and others employ a sort of instrument in form of a dart; but as the position and size of the veins is different, in different subjects, no instrument will ever be found to be useful as the common lancet of a proper face. *Haller's Surgery*, p. 274.

FLEDWITE, or **FLIGHT-WHITE**, in our *Ancient Laws*, a discharge, or freedom, from amercements; when one, having been an outlawed fugitive, comes to the peace of our lord and king, on his own accord, or with licence, Rital.

Others rather take it to denote a snuff, or line, set upon a fugitive to be followed to the king's peace.

FLEECE, the covering of wool from off the bodies of sheep.

FLEECE, the golden, is famous among the ancient writers. It was this that the Argonauts, under the command of Jason, went in pursuit of to Colchis, a province of Asia, now called Mingrelia.

The mystery of the golden fleece is variously explained; either of the profits of the wool-trade in Colchis; or of the gold that they commonly gather there, with fleeces, in their rivers. *Arbuth. Diss.* p. 224. See **ARGONAUTA**.

FLEECE, order of the Golden. See **GOLDEN FLEECE**.

FLEET, a number of vessels, going in company, whether on a design of war, or commerce.

In times of peace, merchants ships go in *fleets*, for their mutual aid and assistance; in times of war, besides this security, they likewise procure convoys of men of war; either to escort them to the places whither they are bound, or only a part of the way, to a certain point or latitude, beyond which they are judged out of danger of privateers, &c.

The admirals of his majesty's fleet are classed into three squadrons, viz. the red, white, and blue. When any of these officers are invested with the command of a squadron, or detachment of men of war, the particular ships are distinguished by the colours of their respective squadron; the union is common to them all, and in those of the red squadron it is displayed on a red field; on a white for those of the white squadron, and on a blue field for the blue squadron. A *fleet*, whenever it be the number of ships of which it consists, is usually divided into three **SQUADRONS**, and these again, when the ships are numerous, into three **DIVISIONS**, distinguished by a particular flag or pendant, and usually commanded by a general officer. The admiral, or principal officer, commands the centre; the vice-admiral, or second in command, superintends the van-guard; and the operations in the rear are directed by the rear-admiral, or officer next in rank. The most convenient order of a *fleet*, proceeding on a voyage, is that in which it is ranged into three lines or columns, each of which is parallel to a line close-ordered, according to the tack on which the line of battle is designed to be formed. The *fleet* being thus more inclosed, will more readily observe the signals, and with greater ease form itself into the line of battle. See **ENGAGEMENT**.

The Spanish *fleet* sent against England by Philip II. consisted of a thousand vessels. In the East there have been *fleets* seen of three thousand vessels.

Merchant *fleets* generally take their denomination from the place they are bound to; as the *Turkey fleet*, *East India fleet*, &c.

The Spaniards call simply the *fleet*, or *flota*, a certain number of vessels, belonging partly to the king, and partly to merchants, sent every year to Vera Cruz, a port of New Spain.

The *flota* consists of the captain, admiral, and patch or pinnace, which go on the king's account; and about sixteen ships, from four hundred to a thousand tons, belonging to particular persons. They are all of heavy laden, both going and coming, that they have much ado to defend themselves when attacked. The *flota* put out from Cadix at the month of August, and makes it eighteen or twenty months before it returns.

The *flota* sent annually from the same port to Peru, they call the **CALLEDO**.

When the two *fleets* put out together, they go in company as far as the Antilles, where they separate; the galleons for Carthagena, and Porto Bello; and the *flota* for Vera Cruz; in their return they join at the Havanna. Of the two *fleets* the *calledo* are the most richly laden; not but the cargo of the *flota* is also very considerable.

FLEET is also a famous prison in London, thus called from the river Fleet, on the border whereof it once stood. To this prison persons are usually committed for contempt of the king and his laws; or upon absolute command of the king, or some of his courts, particularly that of chancery; and lastly, for debt.

FLEETING, in *Sea Language*, is the act of changing the situation of a tack, when the blocks are drawn together; or what is called block and block by sailors. The use of *fleeting* is to replace the mechanical powers into a state of action, and the operation is nearly similar to that of winding up a clock or watch.

FLEGM, **FLEGMATIC**, **FLEGMAGOGUE**, &c. See **PHLEGM**, **PHLEGMATIC**, &c.

FLEMENEPRI, **FLEMENEPRI**, or **FLEMENEPRI**, signifies the receiving or relieving of a fugitive or outlaw.

FLEMESWITE, *Fleta*, who writes of this word, interprets it *habere castella fugitorem*.

FLEMINGIANS, or **FLANDRIANS**, in *Ecclésiastiel History*, a sect of rigid Anabaptists, who acquired this name in the sixteenth century, because most of them were natives of Flanders, by way of distinction from the **WATERLANDIANS**. In consequence of some dissensions among the *Flemings*, relating to the treatment of ecclesiastical persons, they were divided into two sects, distinguished by the appellations of *Flandrians* and *Frieslandians*, who differed from each other in their manners and discipline. Many of these in process of time came over to the moderate community of the *Waterlandians*; and those who remained separate are still known by the name of the *Old Flemings*, or *Flandrians*; but they are comparatively few in number. They maintain the opinion of Menno, with respect to the incarnation of Christ, alleging, that his body was produced by the creating power of the Holy Ghost, and not derived from his mother Mary.

FLEMISH, or the *FLEMISH* tongue, is that which we otherwise call Low Dutch, to distinguish it from the German, whereof it is a corruption, and a kind of dialect. The *Flemish* is the language used throughout the provinces of the Netherlands. It differs considerably from the Walloon, which is a corrupt French. There are several *Flemish* translations of the Bible. In the year 1618, it was decreed by the synod of Dort, that a new *Flemish* version should be made of the whole Scriptures; because the old translation, which had been taken from that of Luther, was full of faults. Accordingly, several persons, learned in the Greek and Hebrew languages, undertook the work; which was published with notes in 1637. This Bible is highly valued by the reformed in Holland, &c. Though M. Simon censures it as being far from the perfection of a just translation.

FLEMISH bricks. See **BRICKS**.

FLESH, *Cors*, in *Anatomy*, a similar fibrous part of an animal body, soft and bloody; being that whereof most of the other parts are composed, and whereby they are connected together.

Flesh is properly understood of each part of the body where the blood-vessels are so small, as only to retain blood enough to preserve their colour red. The ancients accounted five different kinds of *flesh*; the first *muscular*, *flesum*, or *flesum*; as the substance of the heart, and other muscles; the second *parenchymatous*, as that of the lungs, liver, and spleen; the third *viscerous*, as the *flesh* of the stomach and intestines; the fourth *glandular*, as that of the breasts, pancreas, tonsils, &c. and the fifth *serous*, as that of the gums, glans of the penis, the lips, &c.

The moderns admit only of one kind of *flesh*; viz. the muscular, consisting of little tubes and vessels, with blood therein; so that *flesh* and muscular parts of the body with them are the same thing.

Sometimes, however, they apply the terms to the glands which they call, by way of distinction, *glandular flesh*. As to the parenchymatous, they are now found to be quite other things than the ancients imagined. The lungs are only an assemblage of membranous vessels, indurated with air; the liver a collection of glands, wherein the bile is separated; the spleen, a heap of vessels, full of blood; and the kidneys, like the liver, a mass of glands for separating of the urine.

FLESH is also used, in *Theology*, in speaking of the mysteries of the INCARNATION and eucharist.

The word was made *flesh*, *Verbum caro factum est*.

The Romanists hold, that the bread in the sacrament of the supper is turned into the real *flesh* of Jesus Christ. See **TRANSUBSTANTIATION**.

FLESH, *flegum*. See **FUNGUS**.

FLESH is sometimes also used by botanists for the soft pulpy substance of any fruit, inclosed between the outer rind or skin, and the seeds, or stone; or for that part of a root, fruit, &c. fit to be eaten.

FLESH-color. See **CARNATION**.

FLESHY *flesum*. See **FIBROUS** roots.

FLESHY, in *Liberty*, a name used by some authors for the common *FLAUNDER*; the *PASER flauitulus* of most writers.

FLE, *milch*, denotes milk that has been skimmed; or from which the cream has been taken.

FLEUR-DE-LIS, **FLEUR-DE-LIS**, **FLEUR-DE-LIS**, and **FLEURY**, in *Heraldry*. See **FLOXY**.

FLEXIBLE, in *Physic*, is applied to bodies that are capable of being bent, or changed from their natural form and direction.

A body is not capable of being inflected or bent, unless the whole thereof be at rest. In bending a body, it constitutes, as it were, two levers; and the point it is to be bent in, is a fulcrum; hence, as a moving power, the further it is from the fulcrum, acquires a greater force; the longer the flexible body is, the easier it is bent.

FLEXION, in *Anatomy*, &c. is applied to the motion of an arm, or other member, whereby it is bent.

The arm has a motion of *flexion*, and another of extension.

The motion of *flexion* is, when the radius and humerus approach each other, and form an angle at the elbow.

FLEXOR, in *Geometry*. See **FLEXURE**.

FLEXOR, in *Anatomy*, a name given to several muscles in respect of their action; viz. the bending of the members, or joints, in opposition to the extensors, which open and stretch them; among which are the following: **FLEXOR capitis** is a muscle of the head, called also *arctus major anticus*.

FLEXOR carpi radialis, called also *radialis internus*, rises from the inner protuberance of the humerus; and running along the radius, is inserted into the upper part of the bone of the mesocarpus, which is joined with the fore-finger.

FLEXOR carpi ulnaris, called also *ulnaris internus*, arises tendinous from the inner protuberance of the humerus, and upper part of the ulna, upon which it runs along, till, passing under the ligamentum annulare, it is inserted by a short strong tendon into the fourth bone of the first row of the carpus. See *Tal. Anat. (Myol.) fig. 2. n. 24*.

Both these muscles bend the wrist. See **ULNARIS internus**. **FLEXOR digitorum pedis** *occipitalis*, a flat and pretty long fleshy muscle, situated obliquely under the sole of the foot, and from its situation and figure, formerly called *caro plantæ pedis quadrata*.

It is fixed posteriorly by one fleshy portion, in the lower side of the os calcis, and in the anterior tuberosity on that side, and by the other in the ligament which joins this bone to the albugaleus. From thence the two other portions run obliquely to the middle of the sole of the foot, and there unite in a flat, long, and irregularly square muscular mass, which fixed to the outer edge of the fasciculus of tendons of the *flexor longus*, to which it serves as a *frænum* in that place.

FLEXOR pollicis pedis brevis arises from the middle of the calciform bone. It is short, thick, and fleshy, forming two; and, running over the termination of the petronus, has a double insertion in the ossa tarsales.

FLEXOR pollicis pedis longus. This is a muscle of the toe; it is derived from the back part of the cubus, with a double order of fibres, and runs tendinous under the inner ankle, and through the channel in the inner part of the bone of the heel, to its insertion at the extremity of the great toe, on the under side.

FLEXOR profundus, in *Anatomy*, a name given by Cowper and some other writers to the muscle of the foot, called also the **PERFORANS pedis**, and the *perforatorius* by Rolan, and some others.

FLEXOR primi interdigitalium digitorum pedis. See **LUMBRICALIS pedis**.

FLEXOR secundi interdigitalium digitorum manus. See **PERFORANS manus**.

FLEXOR tertii interdigitalium digitorum manus. See **PERFORANS manus**.

FLEXOR tertii interdigitalium digitorum pedis. See **PERFORANS pedis**.

FLEXORES primi interdigitalium digitorum manus, are muscles of the fingers, called also *lumbricales manus*. See **LUMBRICALIS**.

FLEXORES pollicis manus, are the two muscles serving to bend the thumb.

The first, called *flexor tertii interdigitalium*, &c. arises from the internal protuberance of the humerus, and part of the radius, by different orders of fibres, and, passing under the ligamentum annulare, is inserted into the third bone of the thumb. The second, called *flexor secundi interdigitalium*, &c. arises from the base of the carpus, and annular ligament; and is inserted into the second bone of the thumb.

FLEXORES secundi interdigitalium digitorum pedis. See **PERFORANS pedis**.

FLEXURE, or **FLEXION**, in *Geometry*, is used to signify, that a curve is both concave and convex, with respect to a given right line, or a fixed point. And the point which

which limits the convexity and convexity, is called the *point of contrary flexure*. See *RETROGRADATION of curves*.

As to the method of finding the points of the contrary flexure see *INFLECTION*.

FLIDE-THRIFT, or more truly *SLIDE-THRIFT*, is the game we now call *forisecur*. It is otherwise called *flageolet*, and is mentioned in the statute 33 Hen. VIII. cap. 9.

FLIE, or *FLY*, that part of the mariner's compass on which the thirty-two winds are drawn, and over which the needle is placed, and fastened underneath.

FLIGHT, the act of a bird in *FLYING*; or the manner, duration, &c. thereof.

The *FEATHERS* of birds are admirably contrived and fitted for the ease and convenience of flight.

Almost every kind of bird has its particular flight: the eagle's *flight* is the highest; that of the hawk and vulture are noble, and are fit for high enterprise and combat. The *flight* of some birds is low, weak, transient, and, as they call it, *terre à terre*; the *flight* of the partridge and pheasant is but of short continuance; that of the dove is laboured; that of the sparrow undulatory, &c.

The augurs pretended to foretell future events from the flight of birds.

FLIGHT. In meeting the leather in the works at Newbury, there is a substance which flies away in the fluke, which they call the *flight*.

They find it sweetish upon their lips, if their faces happen to be in the way of the fluke, which they avoid as much as possible. This, falling on the grass, kills cattle that feed thereon; and, being gathered, and carried home, kills rats and mice in their houses; that which falls on the sand, they gather, and melt upon a flag-hearth, into shot, and steel-ball.

FEIGHT, caput, in some *Cassins*, is a compass of ground, such as a capon might fly over, due to the eldest born of several brothers, in making partition of the father's effects with them, where there is no principal man in a lordship. It is usually estimated by a bow-shot.

FLIGHT of a staircase. See *STAIRCASE*.

FLIGHT in heraldry. See *VOL*.

FLING, in the *Manège*, is the fiery and obstinate action of an untamed horse.

To fling like a cow is to raise only one leg, and give a blow with it.

To fling or kick with the hind legs. See *YERRING*.

FLINGING, among *Bowlers*. See *BOWLING*.

FLINT, *flint*, in *Natural History*, the name of a genus of tempestuous stones, the matter of which is a crystal, debased by an admixture of a peculiar and appropriated earth, which is of a blackish grey, always free from veins, but, according to the different quantity and disposition of the earth in its composition, subject to clouds of a darker or paler colour, and naturally interwoven with a thin whitish crust.

Naturalists, in general, have accounted various species of *flint*, but erroneously; nature has established it into a genus of itself, and allowed no other species than one, which is ever composed of the same matter, and differs only in the proportion of its admixture. When crystalline matter is debased by earths of other colours, or clouded and veined, it ceases to be *flint*, and becomes the pebble, the agate, or the onyx; and for want of attending to this distinction, many have described these variously-coloured bodies twice over; once under the name of coloured *flints*, and a second time under that of *English agates*, &c.

The characters of genuine *flint* are, that it is a stone of an extremely fine and even texture; of a very uncertain surface, sometimes rough, sometimes smooth; of a colour always, in some degree, between blackish and whitish, unless accidentally tinged, as all other fossils are subject to be; very readily giving fire with steel; not fermenting with acids. Hill's *Hill of Poils*, p. 508.

Flints are generally found in beds of chalk and sand, but never forming entire strata of rock, as Jasper does. By long exposure to air and sun, they seem to decay, to lose their lustre, and their firmness of texture, and to be changed into a white calcareous earth or chalk; and on this account they are almost always found covered with a white chalky crust. *Flint* belongs to the class of vitrifiable matters, because it is used in one of the principal ingredients of making GLASS.

The sparks of fire which are produced by striking *flint* against steel, are of the number of those things which nature has made familiar to us, but in which we might find much matter of inquiry, if we would give way to reason on the subject.

The striking fire in this manner has probably been as old as the knowledge of steel; and hence the microscope has

been familiar among us, it has been discovered, first by Dr. Hook, (See *Micrograph*, 1665, p. 44.) that these sparks are so many spherical balls of iron detached by the blow from the main, and rendered by the heat of a fort of scoria. Kemp de Kenyck, a very ingenious chemist, proposed it as a problem worthy the attempts of the curious to solve, and proposed the whole in these words; when a *flint* and steel are struck together, if the sparks are received upon a white paper, they are found to be round masses, which examined by the microscope, are found to be melted and scorified or vitrified iron, which will no longer answer to the magnet: it is therefore demanded, 1. Which of the two instruments contributes most to this change in the iron? 2. What substance it is that is employed to this purpose? 3. In what manner the operation is performed? and 4. Why if iron be used instead of steel, the sparks are very few or none, when with steel there are so many? These questions have appeared almost unanswerable, because people scarce knew how to conceive, that iron which requires for long continued, and so violent a fire to put it in fusion, could by means only of a slight blow, be not only melted, but destroyed as it were. The most eminent persons of the time declined engaging in the attempt, and Mr. Muschenbroeck, from whom a solution was expected by many, at length referred the whole to Mr. Reaumur, who had some time before published a treatise upon iron and steel, and was therefore judged to have most considered the metal in both those states.

This gentleman accepted the task, and attempted the solution of the problem by resolving these questions. 1. By what means the iron is in this act converted into scoria? 2. By what methods it can be so destroyed? 3. How it comes not only to be reduced to scoria, but to be in a state of fusion, and truly rendered liquid? and 4. Why iron gives less as well as fewer sparks on collision with *flint* than steel does? The nature of iron is well enough known for us to be assured that it contains a large portion of inflammable matter, and that it is never ductile, but while it has a quantity of that inflammable matter in it, and that when that is wholly taken from it, it becomes friable, and is reduced to a sort of scoria, analogous to common vitrified matters.

What most conduces to the explanation of the given problem, is, that this inflammable matter contained in iron is very easily separated when iron is heated in an open fire, which is evidently seen, in that it is impossible to heat a bar of iron in a smith's forge, so much as to make it ready for working or joining with another bar, without reducing its whole surface to scoria, or a friable matter which is all thrown off from the bar by the blows of the hammer.

The smaller and thinner a piece of iron is, the more easily it is reduced to scoria, and it is easy to conceive from hence, that in pieces extremely small, there requires no more than the once thoroughly heating them to reduce the whole to scoria; and it is easily proved by experiment, that the flame of a candle being applied to a fine small piece of filings of steel, will soon make it red hot; that if it be then suffered to cool and laid on a white paper, it will be found much to resemble the sparks thrown off by *flint* and steel, and will be reduced to scoria and be friable under the nail, like a piece of charcoal.

It appears then, that there requires but an instant of time to give a red heat to a small particle of iron; and also that when that heat has been given, the particle must have lost that inflammable matter which caused its ductility, and consequently must be reduced to scoria; and hence it appears not wonderful, that the very small piece or particle of steel which is struck off by the *flint*, should be divested of its inflammable matter, and with it of its ductility, by being kept red-hot in the open air, only so long as it was falling from the steel to the paper: that is placed to receive it. The extreme smallness of the particle gives power for so short a heat to destroy its inflammable matter, in which its ductility consists; and therefore to reduce it to a matter no longer ductile, that is, into scoria; and we find that if a parcel of fine filings be dropped through the flame of a lamp driven into an horizontal direction by the blast of a blow-pipe, they will in the instant of their passing through that flame, sparkle and become ignited; and if they are received on a white paper placed underneath, the smallest particles will be found round and friable, reduced to scoria, no way differing from the little globules of scorified steel, which are struck off from the *flint* and steel in giving fire by their collision.

When we have occasion to melt larger parcels of steel or iron, we are obliged to have recourse to such substances to mix with them as will replace with increase that inflammable matter which the fire drives off: the substance of this

this kind are common sulphur, orpiment, arsenic, and the like; and by means of these, it is soon made to run like lead.

Mr. Reaumur having given these hints for explaining the occasion of iron's being found scorified by the short heat it receives from the collision of *flint* and steel, proceeds to account for the reason why iron yields fewer sparks with *flint* than steel does.

On this occasion he observes, that he accidentally had discovered a new phenomenon of iron, in giving the process of a high, great light would be thrown into this subject: the method of making it was this; having inclosed some iron in a crucible, he threw in, at several times, twice the quantity of iron reduced into thin plates; the whole soon melted together, and became one mass, which when this had been cast into a mould and was become cold, it afforded a long train of sparks on being filed with a common coarse file. The sparks were much larger than those produced by a collision of *flint* and steel, and the larger of them far more to the paper placed to receive them; but upon examination, these were all found to be melted in the manner of the sparkling particles struck off from steel, not only burnt, but melted; and that more perfectly than the others from the common collision with *flint*. If after all this, it be asked, why steel yields much more numerous sparks than iron, the answer is plain, that the difference of hardness alone is sufficient to occasion it; but granting even that steel and iron were of equal hardness, steel has the same advantage of iron in this respect, that the before mentioned mixture of iron with antimony has over plain iron, in that it contains much more of the inflammable matter than the iron does, and this inflammable matter it also more equally distributed through all its surface.

It may also be judged, that the *flint* not only contributes by its hardness to the sending off the sparks, but also by its fulphury, what the blow dislodges from it of this kind and puts in violent motion, probably having no small effect both in the fusion and scorification of the metal. That all *flints* contain a large quantity of sulphur is plain, from the sulphurous fumes they afford on being struck together; and the sparks which are produced by striking iron against iron are probably affected in the same manner by the fulphur of the metal dislodged from the adjoining part by the blow.

One great proof of the sparks being melted and rendered globular by means of the labour of the *flint* is, that sparks may be struck from steel, in the same manner by glass as by *flint*; but in less quantity; these having been received on a paper, were examined by Mr. Reaumur, and were found to be fusible, of an irregular figure, having never been melted, and therefore never reduced to the globular shape of the others. In regard to the great change wrought in iron by this operation, or its being, according to the words of Rump, destroyed, no longer retaining its great character of being attracted by the loadstone, Mr. Reaumur willing to try the experiment before he reasoned upon it, found this assertion not to be a fact, or at least not a general one.

All the several kinds of sparks which he mentions, those produced by the common collision of *flint* and steel, those by dropping steel filings through the flume of a lamp, and even those from the filing of the antimonialized iron, all as readily answering to the loadstone as common filings of iron; so that in this case sometimes happen, and iron be liable than to be destroyed, it is however no general fact, but a very rare and extraordinary one. *Memoirs Acad. Scienc. Par. 1756.*

FLINTS, in the Glass-trade. The way of preparing *flint* for the glass operations in the glass-trade is this. Choose the hardest *flints*, such as are black and will resist the file, and wash green when calcined in the fire. Cleanse them of the white crust which adheres to them, then calcine them in a strong fire, and throw them while red-hot into cold water; wash off the ashes that may adhere to them, and powder them in an iron-mortar, and sift them through a very fine sieve; pour upon this powder some weak aqua fortis, or the phlegm of aqua fortis, to dissolve and take up any particles of iron it may have got from the mortar; stir this mixture several times, then let it settle, and in the morning pour off the liquor, and wash the powder several times with hot water, and afterwards dry it in a fire. You will thus have a powder for making the perfect glass as perfectly fine and faultless, as if you had used rock crystal itself. *Cramer's Art of Glass-making, p. 438.*

The washing off the ferruginous particles with aqua fortis is not necessary, when the glass intended to be made is to be tinged with iron afterwards; but when meant to be of pure white, this is the method that will secure whiteness.

FLINT, in working.—The art of cutting or rather breaking *flint* stones into uniform figures, was by some supposed

to be one of the arts now lost. That it was known formerly appears from the ancient Bridewell at Norwich, from the gate of the Austin Friars at Canterbury, that of St. John's Abbey at Colchester, and the gate that formerly stood near Whitehall, Westminster.

But that the art is not lost, and that the French know it, appears from the platform on the top of the royal observatory at Paris, which, instead of being loaded, is paved with *flint*, in the manner here mentioned. But we are not that this art is any where described. *Phil. Trans. N.º. 477, p. 521, and Note last.*

FLINTS, or flint glass, a name given by some to a preparation made of *flint* stones of *flint* extended and powdered, and mixed with two ounces of salt of tartar; these being melted together in a large crucible by a strong fire, run into a glass, which quickly and strongly attracts moisture from the air, and is entirely soluble in water, except a very small portion of earthy matter: this glass being afterwards powdered and fit in a collar, runs into an oil of deliquescence; with this and the case of any metal is prepared one of the *best* *flint* *varieties*. If any acid be added to the liquor of *flint* to saturate the alkali, the *flint* which was kept dissolved in water by means of this alkali will be now precipitated in the state of a fine earth, which earth is entirely soluble by acids.

FLINT MALT. See WALK.

FLIP, a sort of liquor drink, made of malt liquor, brandy, and sugar, mixed.

FLITTER-ADULT, in Zoology. See BAT.

FLAX seed, in Botany, a species of *wheat* *cracca*, which grows in uncultivated places, and by the side of hedges in many parts of England; it flowers in June, and the seeds, which ripen in August, are greatly recommended by some for the gravel and retention of urine.

FLOAT, or FLEET. See FLOTA, and FLEET.

FLOAT of a fishing line, See FISHING-FLOAT.

FLOAT, sometimes called *ammunition*, also denotes a certain quantity of pieces of timber joined together with rafters abut, thrown into a river, to be conveyed down the stream; and even sometimes to carry burdens down a river with the stream. The invention of *floats* is of great use; it is said to have been first put in execution at Paris, in the year 1618.

FLOAT-BARRELS, those barrels fixed to *water-wheels* of underflux mills, serving to receive the impulse of the stream, whereby the wheel is carried round.

It is a disadvantage to have too great a number of *float* *boards*; because when they are all struck by the water in the best manner that it can be brought to adapt them, the form of all these impulses will only be equal to the impulse made against one *float-board* at right angles, by all the water coming out of the pen-flush, through the opening. So as to take place on the *float-board*. The best rule in this case is, to have just so many, that each of them may come out of the water as soon as possible, after it has received and acted with its full impulse; or, which comes to the same thing, when the succeeding one is in a perpendicular direction to the surface of the water. As to the length of these *float-boards*, it may be regulated according to the breadth of the stream. See Desaguliers, vol. II. p. 425.

FLOAT GRASS, in Botany. See GRASS.

FLOATGAGES. See FLOATGAGES.

FLOATING-bridges, a bridge consisting of several boats covered with planks; which ought to be so solidly framed as to bear both bodies and cannon. See BRIDGE.

FLOATING-ISLANDS. See ISLAND.

FLOATING-VEGELS. See BOAT, VEGEL, &c.

FLOATING, in Husbandry, is the sowing or watering of meadows.

FLOOD-PAPER. See PAPER.

FLOOD, a deluge or inundation of waters.

FLOOD is also used in speaking of the TIDES. When the water is at lowest, it is called *flint*; when rising, *spring*, or *ad-flood*; when at highest, *high flood*; when beginning to fall, *ebb-water*.

FLUTTER-MARK, the mark which the sea makes on the shore, or flowing water, and the highest tide: it is also called *high-water mark*.

FLOOD SAND. See SAND.

FLOOD of an anchor. See ANCHOR.

FLOORING, in Mining, a term used to express a peculiarity in the load of a mine. The load or quantity of ore is frequently interested in its coarsety, by the crossing of a vein of earth or stone, or some different metallic substance; in which case the load is moved to one side, and this transient part of the load is called a *fluting*.

FLOOR, in Building, the underface of a room, or that part we walk on.

Flors are of divers sorts; some of earth, some of brick, others of stone, others of boards, &c.

Carpenters, by the word *flor*, understand as well the frame work of timber, as the bowling over it.

For brick and stone Floors, for PAVEMENT.

For bricked Floors, it is observable, that the carpenters never flow their joints with bands, till the circles are set up, and also inclosed with walls, lest the water should injure the flooring. Yet they generally rough-plan their boards for the flooring, before they begin any thing else about the building, that they may set them by to dry and season, which is done in the most careful manner. The best wood for flooring is the fine yellow deal well seasoned, which, when well laid, will keep its colour for a long while; whereas the white fir becomes black by often washing, and looks very bad. The joints of the boards are commonly made plain, so as to touch each other only a hair, when the fluid is not quite dry, and the boards shrink, the water runs through them, whenever the floor is washed, and injures the ceiling underneath. For this reason they are made with feather edges, so as to cover each other about half an inch, and sometimes they are made with grooves and tenons; and sometimes the joints are made with dovetails, in which case the lower edge is nailed down and the next drove into it, so that the nails are concealed. The manner of measuring floors is by squares of 10 feet on each side, so that taking the length and breadth and multiplying them together and cutting off 2 decimals, the content of a floor in squares will be given. Thus 18 by 16 gives 288 or 2 squares and 48 decimal parts.

Floors, earthen, are commonly made of loam, and sometimes, especially to make mats on, of lime, and brick-dust, and gun-dust, or anti-dust from the forge.

Osseous and fine clay, tempered together, is High Pasture, make the finest floor in the world.

The manner of making earthen floors for plain country habitations is as follows. Take two thirds of lime, and one of coarse sand well sifted, with a small quantity of loam clay; mix the whole together, and temper it well with water, making it up into a heap: let it lie a week or ten days, and then temper it over again. After this, heap it up for three or four days, and repeat the tempering very high, till it becomes smooth, yielding, tough, and heavy. The ground being then levelled, lay the floor somewhat above 2, or 3 inches thick, making it smooth with a trowel: the better the season is the better; and where it is thoroughly dried, it will make the best floor for houses, especially in the south.

If any one would have their floor look better, let them take lime made of red-flints, well tempered with whites of eggs, covering the floor about 3 or 4 inch thick with it, before the under flooring is too dry. If this be well done, and thoroughly dried, it will look when rubbed with a little oil, as transparent as metal or glass. In elegant houses floors of this nature are made of stucco or of plaster of Paris beaten and sifted, and mixed with other ingredients.

Floors of a ship, strictly taken, is only so much of her bottom as the keel on, when aground.

Such ships as have long, and withal broad floors, lie on the ground with most security, and are not apt to feel, or sit on one side; whereas others, which are narrow in the floor, or, in the sea-phrases, *cracked by the ground*, cannot be grounded without danger of being overturned.

Floor-timbers, in a ship, are those parts of a ship's timbers which are placed immediately across the keel, and upon which the bottom of the ship is framed; to these the upper parts of the timbers are united, being only a continuation of floor-timbers upwards.

FLORALIS. See **LEAS.**

FLORALIS, Latin, or FLORAL games, in Antiquity, were practised in honour of Flora, the goddess of flowers.

They were celebrated with banquets and debaucheries. The most licentious discourses were not enough, but the comedians were called together by the sound of a trumpet, and made their appearance naked, and entertained the people with indecent fumes and postures: the comedians appeared after the same manner on the stage. Val. Maximus relates, that Cato being once present in the theatre on this occasion, the people were ashamed to sit for such unbecoming representations in his presence till Cato, apprised of the irreverence and respect with which he regarded them, withdrew, that the people might not be disappointed of their accustomed diversion.

There were divers other sorts of shows exhibited on this occasion; and, if we may believe Suetonius in Caligula, c. vi. and Vopiscus in Carinus, these princes presented elephants dancing on ropes on these occasions.

The *Floralis* according to Pliny, lib. xiii. c. 20. were instituted by order of an oracle of the Nymphs, on the 28th of April; not in the year of Rome 1231, as we commonly read it in the ancient editions of that author, but in 1211, as F. Harduin has corrected it, but, as Vossius reads it, in 513. Though they were

not regularly held every year, till after 450. They were chiefly held in the spring time, in the Porcia-street; some will have it there was a street for the purpose, on the hill called *Floralium*.

The product Flora is by some said to be the same with the *Chlois* of the Greeks. *Chlois* is a Greek word, that this Flora was a famous courtesan of Rome, who, being enriched herself by prostituting herself to the prince of Rome her heirs, on condition that they should celebrate the anniversary of her birth-day, with games and feasts above mentioned. Some time after was the custom, judging such a foundation unworthy the dignity of the Roman people, to ennoble the extraordinary person Flora into a goddess, whom they supposed to preside over flowers; and to make it a part of religion to render her propitiations, that it might be well with their gardens, vineyards, &c. This is the common account; but Voltaire de *Idolol.* lib. i. c. 12. can by no means allow the goddess Flora to have been the courtesan above mentioned: he will rather have her a Sabine deity, and thinks her worship might have commenced under Romulus. His reason is, that Varro, in his fourth book of the Latin tongue, ranks Flora among the deities, to whom Tatius, king of the Sabines, offered up vows, before he joined battle with the Romans. Add, that from another passage in Varro it appears, that there were priests of Flora, with sacrifices, &c. as early as the times of Romulus and Numa.

FLORAL games. There is also a kind of *Floral game* observed at this day in France; first instituted in 1574.

The design and edification were owing to seven persons of distinction, lovers of poetry, who about All-Saints-day, in 1572, sent a circular letter to all the Provençal poets, called *Thoulousiens*, to meet at Thoulouse on May-day following, there to rehearse their poems; promising a prize of a violet of gold to the person whose piece should be judged the best.

The capitouls found the design so good, that it was afterwards resolved, at a council of the city, to continue it at the city-charge; which is still done in a manner that does honour to the place.

In 1575, a chancery and secretary of the new academy were chosen; and the seven indicators took the quality of maintainers thereof. Two other prizes were afterwards added to the violet; viz. an eagle for the second prize, and a panther for the third. It was also decreed, that the person who bore away the first prize, might demand to be made bachelor; and that whoever bore away all three, should be created doctor in the *pay fenne*, that is, in poetry.

There is a register of these games kept at Thoulouse, which gives this account of their origin; though others represent the matter differently. It was an ancient custom they say, for the poets of Provence to meet yearly at Thoulouse, to confer together, criticize their verses, and receive a prize allotted to the best performances. This held till about the year 1540, when a lady of quality left the best part of her fortune to encrease the custom, and bear the expense of prizes; the number of which she increased, ordering an eagle for a panther, a panther, a violet, and a hawk: the three first, a culot high; and worth fifteen pistoles a piece.

The ceremony begins on May-day, with a solemn mass, music, &c. The corporation attend; and poems are recited every day: the third day a magnificent treat is given by the magistracy, &c. and that day the prizes are adjudged. The three prizes are the reward of three different kinds of compositions; viz. a poem, an eclogue, and an ode.

FLORALIA, in Antiquity, a general name for the feasts, games and other ceremonies, held in honour of the goddess Flora.

FLORES argenti, in Natural History, a name given by some to the earth called by the generality of authors *lucida humus*. It has both these names from its being supposed to partake of the nature of silver.

Flowers marinated, a name given to a preparation of the nature of what was formerly called *case veneris*. These flowers are thus prepared: take of washed colicoster, or green violet, or of iron filings, one pound, of sal ammoniac, two pounds: mix them, and subliming them in a retort, and mixing again the bottom with the flowers, renew the sublimation till the flowers acquire a beautiful yellow colour. To the residue may be added half a pound of fresh sal ammoniac, and the sublimation repeated, and the same process may be continued as long as the flowers arise duly coloured. Pemberton's Lond. Disp. p. 215.

FLORET, in Anatomy, is a little robe expanded at the top usually into five segments, and fitting upon the embryo of a single seed, from the inner part of the *flor* arise five flamina, which, uniting together, form a sheath; from the embryo of the seed arises a style, which passes through the sheath, to which it is connected; and is terminated

minated by a bold stigma, which is generally reflexed. These are *Berm-apothee*.

FLORET, flos, (botanists of the bafe, and afterwards expanded in the form of a tongue; these generally form the rays of compound flowers, and are female.

FLOREDA, is that enriched and heightened with figures and flowers of rhombus. See **STYLAR**.

Longinus uses the terms *flores* and *officines* indifferently, and lays them down at quite contrary to the true sublime.

FLORELIUM, FLORELIUM, a name the Latins have given to what the Greeks called *anthologion*, **ASTROLOGY**, viz. a collection of those pieces, containing the finest and brightest things to their kind.

FLORELIUM is also particularly used as a kind of breviary, in the Eastern church, compiled by Arcadius, for the convenience of the Greek priests and monks, who cannot carry with them, in their travels and pilgrimages, all the volumes wherein their office is dispersed.

The *Florilegium* contains the general robes, psalter, exhortations, the homilegium, and the office of the feast, &c.

FLOREIN is sometimes used for a coin, or real money; and sometimes for an imaginary money, or money of account.

FLOREIN, as a coin, is of silver value, according to the diverse mints, and diverse countries where it is struck. Pieces under this denomination were especially very frequent in commerce; at present they are less common, though there were abundance of them struck in Holland, of English silver, during the war, which was terminated by the treaty of Ryswick. In all appearance they took their name from the place where they were first struck, viz. the city of Florence. Their use is about the year 1221; though others ascribe the name to a fleur-de-lis, which was struck on one side.

Villani observes, that there were gold *florins* in the year 1257, from which time the names *FRANC* or *FRANCO* became applied to the gold coin, which till that time had been called *florin*, *florino*. See **COIN**.

FLOREIN, as a *monnaie d'argent*, is used by the Italian, Dutch, and German merchants and bankers, in keeping their books, and making up their accounts. But this *florin* is very diverse, and admits of different divisions. See **COIN**.

FLOREIN, or **FLOREINER**, was also a gold coin, struck in England in the eighth year of Edward III. of the value of six shillings.

Camden says, it was so called, because made by Florentines. Fabian observes, the *florin* were not of so fine gold as the nobles and half-nobles of that prince.

But what is most observable is, that Fabian calls the *florin* a penny, value 6d. the half *florin*, a halfpenny, value 3d. the quarter *florin*, a farthing, value 1d. These words we often meet with in old histories and accounts, applied to several coins, as *royals*, *angels*, &c. where we are therefore only to understand by *penny* or *denier* the whole, by *thous* the half, and by *quadrans* the fourth part, or farthing.

By inclosure of the mint, in 18 Edw. III. every pound weight of old standard gold was to be coined into fifty *florins* or *florins*, to be current at six shillings a-piece; all which made in tale fifteen pounds, or into a proportionable number of half and quarter *florins*.

FLORENIUM, or **FLORENIUM**, a sect of heretics, of the second century, denominated from its author Florinus, or Flouinus, a priest of the Roman church, deposed along with Hilary, for his errors.

Flouinus had been a disciple of St. Polycarp, along with Irenaeus. He made God the author of evil, or rather asserted, that the things forbidden by God are not evil, but of his own appointing. In which he followed the errors of Valentinus, and joined himself with the Gnosticists.

They had adherents, some given them. Philastrius says, they were the same with the *Carapodians*. He adds, that they were also called *Salutis*, *maiores*, *quia de millibus* *salutis*. St. Jerome calls them *Carapodii*; St. Epiphanius, *Pentecostes*; and Theodoret, *Barbari*, on account of the impurities of their lives. Others call them *Zenobiani*; others *Colobiani*, &c. though for what particular reason, it is not easy to say, nor perhaps would it be worth while to inquire.

FLORENT, a person curious or skilled in flowers; their kind, names, characters, culture, &c.

It is also applied to an author who writes what is called the *flora* of any particular place, that is, a catalogue of the plants and trees which are found spontaneously growing there. The *Flora Lapezica* of Linnaeus, and *Flora Virginia* of Gronovius, are works of this kind; and these authors, as the authors of those works, are properly called *florists*.

FLOREUS, in *Ornithology*, a name by which Aldrovand and some other authors have called the bird commonly known

with us by the name of the *WHINCHAT*, a kind of the *OSANTHE* or *fallow-lark*.

FLOREY, FLOWAY, FLEURY, FLORETTA, FLORETTES, &c. terms in *Heraldry*, used when the outlines of any ordinary are drawn as if trimmed with, or in the form of flowers, lilies, fleur-de-lis, &c. Thus, he bears a cross *flory*, &c. See **Tab. Heraldry**, p. 26.

FLOS, the flower of a plant. It is to be observed that the ancients sometimes called the flammis or threads in the centre of flowers, the *flos*, and not the petals, which we usually call so. Without understanding this, it is not possible to understand many passages in their writings. We find in Avellan, the rose called a yellow flower standing in a purple husk; it is plain by this, that he meant the threads in the middle of that flower, which are of a fine yellow, and are very numerous, by the word *flos*; and he calls the fine purple petals, which we give the flower, only the husk of the flower. In this sense, Virgil is explained to mean the common husk by the name *anella*; he says it has a yellow flower, and purple leaves at the bottom, and they suppose that he meant the flammis or threads, which in the husk are yellow, by the name flower; and the calyx or cup of the flower, which is a purple, by this expression of leaves at the bottom. The ancients in general do not seem determined as to what they would have understood by the word *flos*. In the *herbarius*, Piny calls the cup that yellow part which occupies the centre, and the whitish leaves that surround it, the flower. Piny has been censured for calling this part of the flower the cup; but he does not by this mean to confound it with the green leaves in the generality of plants which surround the flower; he only calls it thus in resemblance to the cups out of which they drink in their infancy.

FLOS ERIN. See **FLOS**.

FLOS UNDESPALIS, in *Botany*, a name given by some to the *polygala* or *STREPTANTHUS*.

FLOS ARGENT. See **FLOS ARGENT**.

FLOS ALB, in *Natural History*, a name given by Swenckfeld, and some other writers, to that salt which is found on the surface of the earth in some parts of Asia in form of an efflorescence, and is called the *Empura sup. nardo*. This salt is evidently the same with the nitre of the ancients. It will ferment with any acid, in the manner of our potash, or other fixed salts, made by fire; and with oil or any fatty substance, boils into a soap. Euelius gives us a great many different places for its production, from which he distinguishes it into several kinds; all these lie in the eastern parts of the world; but to these Wormius adds, that it is found in New Spain. It is always easy to be known, however, in whatever place it is found, being a native alkali salt, perforated like a sponge, and of a fragrant taste. Its principles seem to be a marine and an urinous salt.

That it contains a marine salt seems manifest from this, that it has the same taste in solution, or nearly so, with marine salt; that the particles of it when coagulating in the evaporated water in which they were dissolved, float rise to the top of the surface, as those of common salt do, and that it is always of a spongy texture, or full of holes, which is always the case with those things in which the common salt makes a part, its natural concretions being hollow pyramids. Its containing an urinous salt is plain, from its producing with salt of tartar the same sort of spark that salt ammoniac does, when mixed with that fixed salt.

FLOS CARI, the flower of the *hercynia*, a name given by the alchemists to the *ROS ROCI*, which often appearing after rain, was supposed to fall from heaven. See **FLOS TERRE**.

FLOS MARTIALIS. See **FLOS MARTIALIS**.

FLOS JALIS. The flower of salt flows down with the Nile, and is also found on the surface of some lakes. It is to be chosen of the colour of lilicon, somewhat of a rank smell like *parum*, of a biting taste, and of a fatish substance. What is coloured with minimum, or is grossum, is to be rejected; beside, what is pure and genuine is not to be dissolved but in oil; whereas what is adulterated is partly dissoluble in water.

It is effectual against malignant and phagedenic ulcers; grows in the putrida, and persudencies in the ears; it also cures dimness of sight, and removes specks and albugo from the eyes. It is mixed with plasters and ointments, as also with oil of roses, for the sake of the colour it communicates to them. Taken inwardly, in wine or water, it provokes sweat, disturbs the belly, and incommodes the stomach. It is also an ingredient in *scopa* and *insecmata*, for extenuating the hair. In general it is of an acrimonious and pyrotic quality, as are all salts themselves. Dioscor. lib. v. cap. 129.

FLOS TERRE, flower of the earth, a name given by some of the

FLOWERS, *unappetite*. See MONOPETALOUS, and Tab. VIII. of Botany, Clafs 1, 2, 3, and 4, and Tab. X. Clafs 2.

FLOWERS, *whitish*, are the reverse of the *herbaries*. Linnaeus confines the term to those flowers that want the corolla, though they ought to be furnished with it, and this defect he sheweth chiefly in the want of sufficient heat.

FLOWERS, *papilionaceous*, resemble a butterfly with its wings elevated, and consist of four parts, whereof the uppermost is called *standard*, or *standard*; and the lowermost, as resembling the bottom or keel of a boat: those between the two are called *lateral leaves*, or *als*.

From the bottom of the calyx arises a pistil, which is encompassed with a sheath, or cover, tinged with flammula. This pistil always becomes the fruit, and is usually called the *pod*, in Latin, *Silqua*. See Tab. IX. Clafs 10, and Tab. X. Clafs 22.

FLOWERS, *radiated*. See RADIATED, and Tab. X. Clafs 14. FLOWERS, *reflexed*. See REFLUXED, and Tab. IX. Clafs 6, and Tab. X. Clafs 21.

FLOWERS, *semipapilionaceous*. See SEMIPAPILONACEOUS, and Tab. IX. Clafs 13.

FLOWERS, *sessile*, are such as have no petals, but consist wholly of flammula or threads, with spines at top. See STAMINIFEROUS, and Tab. X. Clafs 15.

FLOWERS, *verticalis*, or *whorled*, are those ranged, as it were, in flammula, rings, or rays, along the stalks, at the base of the leaves: such are those of horehound, daisy, &c.

FLOWERS, *umbelliform*, are those with several leaves disposed in manner of a rosette, and made entire essentially become a rosette of two kinds, joined, before they come to maturity, but afterwards easily separated again.

I have thus denominated, because they are generally furnished by a number of pedicels, which proceeding from the same centre, are branched all around, like the flukes of an umbella. See Tab. IX. Clafs 7. Of this kind are the flowers of fumary, *apricaria*, &c.

FLOWERS, *colours* of. It is generally agreed among the chemists, that all colours arise from sulphur, and that they differ according to the different admixtures of salts with these sulphurs. Perhaps on these principles, it may be possible from some rational conjectures in regard to the origin of colour in the flowers of plants. We know very well that the flowers of all plants abound in an essential oil or sulphur, to which, according to this doctrine, their colours may be rationally supposed to be owing; and though this oil should be proved to be the very same substance in all, yet the variety of colours may be accounted for from it, since we find that one and the same oil, the essential oil of thyme, according to Mr. Crofton's experiments, may be tuned to all the colours that we find in the different flowers of plants, from white to deep black, with all the shades of red, yellow, purple, blue, and green; by mixing it with different substances; and by the same law, the essential oil of plants, while contained in their flowers, may by the different mixtures they meet with, give them all their beautiful variety of colours. See ESSENTIAL OILS.

We know that the infusions of flowers, and of other parts of plants, become red on being mixed with acids, and green on being mixed with alkalis; and there is no reason to doubt, but that it is the sulphureous part of the vegetable in these infusions which thus changes colour on these mixtures. This, however, ought to be proved possible, before it is allowed in argument.

This proof is given in the change of colour before mentioned, which are produced in oils merely by the admixture of different salts; and as all the colours in these are the regular result of certain combinations, there is great reason to believe, that in those plants whose flowers give the same colours, there may be the same combinations.

The principal colours of plants, and their several parts, are green, yellow, red, purple, blue, white, black, and transparent whitishness; all the others are produced by different combinations of these. The green, which is the common colour of the leaves of plants, is probably the effect of an oil varnished in that part of the plant, and there mixed with the fixed and volatile salts of the lip, which remain extended by the earthy particles after most of the aqueous humidity is evaporated, and by that means become in a state to act upon the oil. A clear proof of this, is that if the leaves are covered up in such a manner, that the aqueous humidity of the top cannot evaporate itself, the oil and salts cannot act upon one another as they naturally would, but becoming diffused among so great a quantity of water, lose the colour they would otherwise have obtained together, and become whitish or transparent. This is seen in the obvious influence of sucory and celery, the leaves of both which plants, though

naturally green, become white by being covered up with earth by the gashers.

The leaves of both plants are usually turned red in autumn, or on the brink of the first frosts; the reason of which is, that the leaves, which before being covered up by the cold, the earth, or the frost, in the vessels of the leaves, or at least of the plant, is greatly interrupted; and being detained there, it naturally grows sour, the acidity of this altered juice affecting the green colour, produced by the oil and salts. The sap brings on a red colour, in the way these plants that the essential oil made green by a mixture of oil of tartar, is again changed to red, by adding to it a superabundance of distilled vinegar. Where we find in our common experiments the acids of the mineral kind turning the infusions of flowers red, it is by the analogy of these experiments to be explained, by the analogy of the blue, brown, or other colours, which are the same parts of the plant had made with the same oil.

All the shades and degrees of yellow and lilac colour in the flowers of plants, from white owing to a mixture of an acid in their juices, with their essential oil; as the oil of thyme, which itself has very little colour, is made to pass through all these shades of colours, only by digesting it with distilled vinegar. From the digesting the volatile alkalies, such as spirit of fal ammoniac and urine, with the same oil, it appears that all the shades of red, from the palest first colour, to purple, and even to the violet blue, are only owing to the different admixtures of an alkaline volatile salt of the thymine kind, mixed in different manner with their essential oil.

Black, which is a very uncommon colour in flowers, and which in them ought to be regarded only as a very deep violet, from the effect of an addition of an acid juice to them, already turned purple or violet colour by a volatile alkali.

All the shades of blue and purple form also, by the analogy of the same experiments, to be only the effects of mixtures of alkalies of the fixed and volatile kind, with the oils of plants; since these colours are all produced in these experiments, by mixing the spirit of fal ammoniac, and the oil of tartar with oil of thyme.

The bright green of some flowers seems also to be produced by the same salts, only acting on oils more rarefied. For the oil of thyme of a purple violet-colour altered with rectified spirit of wine, being united with oil of tartar, becomes green. Mem. Acad. Par. 1707. Becomes of opinion, that in many plants the colour of the flowers is wholly owing to the colour of the juices of the root. This he influences in the greatercelandine, whole roots and flowers are of the same yellow colour. The haberny in the panacea, he observes, has both its roots and flowers yellow. The centauria has its roots and flowers both of a pale red, and the saecis indica Adonis, and many other plants, he says, are instances of this. The reason that he assigns for this is, that the more fixed part wherein this colour consists, preserve the same structure, without being at all altered by so long a circulation as that from the root to the flower; and he adds another very remarkable observation, which is, that in all these plants and trees, whose roots and flowers are of the same colour, the juices are more fixed; and therefore, that there are more in for dying than any other coloured woods or plants. Vide Deccase, Mus. de Plants.

Dr. Lewis, in his notes on Neumann's Chemistry, has many curious observations on the colours of plants. There are few of them which are constant themselves, or that can be made durable by art. The only permanent colour is yellow, of leaves, the blue, and the first permanent shades of purple, crimson, red, &c. are very perishable. Many flowers lose their colours on being dried, and especially if they are dried in a dark and not warm place. The colours of some other plants by keeping even in the cabinet of herbs, they very readily they are dried, and the more perfectly so, the more faded from any, so much the looser fit they retain their beauty. The colouring matter of flowers is extracted and applied to other bodies in this manner.

The colour of many blue flowers extracted by infusion in water, but from others, water requires only purplish hue. Of those which have been dried, and are given a blue colour to spirit of wine, I have given an account, and those give a reddish colour. The crimson juice of these flowers is generally blue. The blue juices and mixtures are rendered red by all acids, and the weak fixed red is given to them by concentrated. The yellow also, by maceration, impart a red colour to acid liquors. A fixed and volatile, and lime-water, change their blue colours to green. And these infusions or juices which have nothing of the colour of the flowers, suffer the same changes from the addition of acid and alkaline liquors. Even when the flowers have been kept till their colours are

are lost, their infusions acquire a red colour from acids, and a green colour from alkalis, but in a less degree than when the flowers were fresh. The red colour produced by acids is far more durable than the original blue, applied upon either body, and exposed to air, it gradually degenerates into a faint purple, and at last disappears, without leaving a stain behind. The green produced by alkalis changes to a yellow, which does not fade so soon. The green made by lime water is more permanent and less useful. Green lakes, prepared from blue flowers by means of lime-water, have been used by painters. The flowers of *Lythrum* have been much commended for affording elegant and blue pigments. But Dr. Lewis has not been able to extract from them any blue colour. They retain their colour, when lustily dried longer than other blue flowers, but do not communicate their original colour to any menstruum.

Red flowers readily communicate their colour to water; and those of a full red colour give to a red tincture spirit a deep red tincture, brighter, though somewhat paler, than the flower's infusion. But the light red flowers, and those which are purple, impart little colour to pure spirit. The colours of infusions of these flowers are supposed to be heightened by acids, and to be rendered green by alkalis. But this is not universal. For amongst those examined by Dr. Lewis, the rose colours and purple red were changed by acids nearly as blue flowers are; but the full deep red was not. The deep infusion of red poppies was turned by alkalis not to a green, but to a dusky purple.

Yellow flowers communicate to water and to spirit of wine durable yellow colours, not alterable but in degree by acids or by alkalis; the former only rendering them paler; and the latter, as also alum, rendering them deeper. Wool, or silk, impregnated with a solution of alum or tartar, receives, on being boiled with the watery infusion or decoction, a durable yellow dye. A durable yellow lake is prepared by precipitation with alum an infusion of yellow flowers made in an alkaline ley. In some of the orange-coloured flowers the yellow matter seems to be of the same kind as that of the pure yellow flowers; but the red matter seems to be different from that of the pure red flowers. The yellow matter is extracted from these flowers by water; and the remaining red matter is extracted by spirit of wine, or by a weak solution of fixed alkali in water. Such are the leafy coloured flowers of *Verbascum*. These flowers, after the yellow matter has been extracted by water, and find to give a red tincture to ley, from which a deep red fecula subsides, called *lignum*, *Spargelia*, and *Chenopodium*. This pigment gives a beautiful red colour to spirit of wine, but more to water. The yellow tincture of the leafy, resting on the tips of the filaments of flowers, gives a fine bright yellow colour to spirit of wine, and a duller yellow colour to water. The colours of both the watery and spirituous tinctures were heightened by alkalis, rendered red by acids, and again restored to a yellow by adding an alkali. This is the only known instance of the yellow colour of a vegetable being rendered red by acids.

White flowers, or their expressed juices, impart a green colour to alkalis, but have not been observed by Dr. Lewis to give a red colour to acids. The white flowers of the common wall *Exorhizum* give a deep yellow or orange colour to water, which is affected by acids, by alkalis, and by alum, as the infusions of yellow flowers are. The white flowers of *Arctostaphylos* give a beautiful yellow colour to water acidulated with spirit of nitric. See NEUMANN'S Chem. by Dr. Lewis, p. 430.

FLOWERS, in Gardening, are distinguished into *early*, or *spring* flowers, which flourish in the months of March, April, and May. Of this class are the anemones, daffodils, hyacinths, tulips, jonquils, cowslips, primroses, &c. Summer flowers, which open in June, July, and August, as pinks, gilliflowers, lilies, daisies, campanulas, poppies, ranunculus, &c. Autumnal, or late flowers, denote those of September and October, as the scarlet China, Indian pink and roses, peonies, flowers, &c. Of these flowers, those which flourish all the year, we mean in the flower, or more at least, are called *perennials*. And those which are to be planted or sown fresh every year, according to the season, are called *annuals*.

FLOWERS, preservation of. The method of preserving flowers in their beauty through the whole year has been diligently sought after by many people. Some have attempted it, by gathering them when dry, and not too much opened, and burying them in dry sand; but this, though it preserves their figure well, yet takes off from the vivacity of their colour.

The primrose and cow-slip kind are very eminent instances of the change of colours in the flowers of dried flowers.

elements; for those of this class of plants early dry in their natural shape. But they not only lose their yellow, which might be expected naturally enough, but they acquire a fine deep green, much deeper than that of the leaves in their most perfect state. The colours of all the sister kind lose their native hue, and become of a dead white, so that in dried specimens there is no difference between the fine flowered sister and the white flowered kind. Muntingius gives a method, which is in itself preferable to all others, thus as follows: gather roses or other flowers when they are not yet thoroughly open. In the middle of a dry day, put them into a good earthen vessel, placed within a full the vessel up to the top with clean; and when full, sprinkle them over with some good French wine, with a little salt in it, then let them be in a cellar, tying the mouth of the pot exactly down. After this, they may be taken out at pleasure, and on seeing them in the sun, or within the reach of the fire, they will open as if on the tree, and not only the colour, but the smell will be preserved.

Sir Robert Southwell has communicated to the world a method of drying plants, by which all flowers are preserved in their natural shape, and many in their proper colours. To this purpose two plates of iron are to be prepared of the size of a large half sheet of paper, or larger for particular occasions; these plates must be made of such a nature as to have any power of bending, and there must be a hole made near every corner for the receiving a screw to fasten them close together.

When these plates are prepared, lay in readiness several sheets of paper, and then gather the plants with their flowers, when they are quite perfect; and let this always be done in the middle of a dry day, and then lay the plant and its flower on one of the sheets of paper doubled in half, spreading out all the leaves and petals as much as can be. If the stalk be thick, it must be pared off cut in half so that it may be the less and it may be woody, it may be pared, and only the bark left; when the plant is thus expanded, lay round about it some loose leaves and petals of the flower, which may serve to complete any part that may prove deficient; what is thus prepared, lay several sheets of paper over the plant, and as many under it; then put the whole into the iron plates, tying the papers smoothly on one, and leaving the other evenly over them; then draw them close, and put them into an oven after the bread is drawn, and let them lie there two hours; after this make a mixture of equal parts of aqua-fortis and common brandy, shake them well together; and when the flowers are taken out of the pressure of the plates, rub them lightly over with a camel's hair pencil dipped in this liquor, then lay them upon fresh brown paper, and covering them with some other sheets, press them between this and other papers with a handkerchief, till the wet of these liquors is almost wholly away. When the plant is thus far prepared, take the quantity of a narrow gum dragon, put this into a pint of fair water cold, and let it stand four and twenty hours; it will in this time be wholly dissolved; then dip a fine hair pencil in this liquor, and with a daisy over the back of the leaves, and lay them carefully down on a half sheet of white paper fairly expanded, and press them with some more papers over them. When the gum water is dried, let the pressure and papers be removed, and the whole work is finished. The leaves retain their verdure in this case, and the flowers closely keep their natural colours. Some care must be taken, that the heat of the oven be not too great. When the flowers are thick and bulky, some art may be used to part of their backs, and dispose the petals in a due order; and after this, if any of them are wanting, their places may be supplied with some of the superfluous ones saved from the petals, and if any one of them be lost, it will be prudent to rub them away, and lay down others in their stead; the leaves may be also disposed and situated in the same manner. Another way of keeping both stems and fruit the whole year without spoiling, is ordered by the same author in the following manner: take full-petted, not soundly bloomed, rose, two pounds; a cream-coloured, hand, three pounds; mix all well together, then rubber fruit of any kind, that is, any tulips, with the last context, but do not rub by one into a wide-mouthed glass, leaving them in good order; tie over the top with an elastic, and carry this glass into a dry cellar, and let the whole upon a bed of this prepared matter of four inches thick in a box; fill up the remainder of the box with the same preparation, and let it be under the glass; this over the top of the glass, and round all its sides. Flowers are to be preserved in the same sort of climate in the same manner, and they may be taken up, after a whole year, as plump and as fair as when buried.

FLOWERS, in History. We find flowers in great request at the entertainments of the ancients, being removed by the

the matter of the feast, and brought in before the second course; or, as some are of opinion, at the beginning of the entertainment. They not only adorned their heads, necks, and breasts, with flowers, but often belov'd the beds whereon they lay, and all parts of the room with them. But the head was chiefly regarded. Pater Archael. *Græc.* tom. ii. p. 281. See CARLUS. Flowers were likewise used in the beheading of tombs. Pater Archael. *Græc.* lib. iv. cap. 7. tom. ii. p. 232. See BUNN.

FLOWER, in Architecture, according to Viruvius, is a representation of some imaginary power, by way of crowning, or finishing, on the top of a dome, &c. See TOL. Architecture, fig. 12.

In lieu of this the moderns commonly use a vase, half of the size.

FLOWER-MOURET, *Floris-moret*, in Heraldry, is a bearing anciently of great dignity, being reputed the badge of all flowers; and as such having been in all ages the charge of the royal escutcheon of the kings of France; though time has made the bearing thereof more vulgar. In some coats it is borne singly in others triple; in others it is triune, divided all over the escutcheon.

FLOWER of the capital is an ornament of sculpture, in form of a rose, in the middle of the sweep of the Corinthian column.

In that of the Composite, it is not a rose, not any real, but an imaginary kind of flower.

FLOWERS, in Chemistry, are the fixed and moist subtle parts of dry bodies, raised by fire, intestine vessel's head, and stills; and adhering to them, in form of a fine powder, or dust. Such are the flowers of sulphur, benjamin, &c.

FLOWERS of antimony. See ANTIMONY.

FLOWERS of argentine, or *regulus of antimony*, are made by putting the regulus into an unvarnished earthen pot, placed in a furnace, so that its bottom may be red-hot, while its upper part shall be much cooler. The pot is to be covered with a lid, without letting in, and heat is to be applied for an hour or more. When the pot is cold, its internal surface, and the remaining part of the regulus are found covered with white flowers, in form of beautiful, transparent, and shining needles, which are to be gathered with a feather. After this, a second sublimation may be commenced, and managed in the same manner; and the whole regulus may be changed into flowers. These flowers appear to be nothing else than the earth of regulus of antimony deprived of almost all its phlogiston. They are neither emetic nor purgative; they are soluble in aqua regia.

FLOWERS of arsenic, which are made, as all other flowers are, by subliming ARSENIC, from which they do not differ in their nature and properties.

FLOWERS of bismuth, or *bismuth*, are made by putting a quantity of this resin into a varnished earthen pan, and covering it with another inverted pan of the same ware; and let the edges of these pans be made to fit well to each other, and to be well luted together with paper dipped in pitch. Put the earthen pan containing the bismuth on a gentle fire, and with that the sublimation is performed; when the vessels are cool and unluted, the flowers are to be swept off with a feather. For the properties and medicinal uses of these flowers, see BENJAMIN.

FLOWERS of bluish. See BISMUTH.

FLOWERS of cobalt. See COBALT.

FLOWERS of copper have been prepared by subliming ful ammoniac with the caput mortuum of blue vitriol. See COPPER.

FLOWERS, martial. See FLOWERS MARTIAL.

FLOWERS of sal ammoniac are nothing more than sal ammoniac sublimed; and the sublimation is facilitated by generally mixing with it an equal part of decrepitated common salt. See SAL AMMONIAC.

FLOWERS of sulphur, or *brimstone*, are the vapours of melted brimstone conveyed from an iron pot (in which it is kept boiling) through a proper hose, into a close room or oven, where this vapour condenses into flowers. See SULPHUR.

FLOWER of wheat, rye, and other pulse. See FARINA and FLOUR.

FLOWERS of zinc. See CADMIA and ZINC.

FLOWERS, in the Animal Economy, denote women's monthly purgations, or MENSES.

Nicot derives the word in this sense from *floris*, q. d. *floris*. Others will have the name transferred hence, that word does not denote till they have had their flowers; in that there are a few of flowers of their fruit.

FLOWERS, in Rhetoric, are figures or ornaments of discourse, by the Latins called *figurae*.

FLOWER-LEAF, *Borborachia*. See BARSADOUS flower-leaf.

FLOWER-LEAF, *Epilobium*. See ADENANTHERA.

FLOWER of Brille. See CANYON.

FLOWER-de-lavie, in History. See LAVIE.

FLOWERS, annual, or *perennials*. See ANNUAL flowers, and COB-WEED.

FLOWERS, fast-faded. See MINERAL.

FLOWERS, gentle. See ANNUAL.

FLOWERS, hot-faded. See ANNUAL. See LAVENDER.

FLOWERS, in the field. See CEREALIA.

FLOWERS, in the garden. See CEREALIA.

pot, stop the hole at the bottom with a cork, and lute in the cork with putty, that no water can get through; then fit a board to the top of the pot, and bore six or seven holes in it, at equal distances, to place the bulbs in, and as many smaller holes near them to receive the flicks, which will serve to tie up the *flowers*. Then fill up the pot with water to the brim, and place tulips, jonquils, narcissuses and the like plants in the pot upon the holes, so that the bottom of the roots may touch the water; thus will they all *flower* early in the season, and be much more beautiful than any pot of gathered *flowers*, and will last many weeks in their full perfection. After the season of *flowering* is over, the roots will gradually shrink through the holes of the board, and get loose into the water, but instead of becoming spoilt there, they will soon increase in size, so as not to be capable of coming back, and will produce several offsets. It is natural to try from this the consequence of keeping the roots under water during the whole time of their blowing, and in this manner they have been found to succeed very well, and *flower* even stronger and more beautifully than when in the ground. They may also, with proper care in the degree of heat in the room, be kept *flowering* from before Christmas till March or April. It is not easy in this last manner to manage the keeping of the boards under water, for which reason it is better to procure some sheet lead of about four pounds to the foot, and cut this to the size of the mouth of the pot; in this sheet should be bored holes for the bulbs, and other holes for the flicks; and in order to keep the flicks quit firm, it is proper to have another plate of lead flapped to the bottom of the pot, with holes in it, answering those in the upper plate made for the flicks. The flicks by this means will be kept always perfectly steady, and the roots being kept under water by the upper plate of lead, will *flower* in the most vigorous and beautiful manner imaginable.

Knotches in the side of each lead, will give easy passage to the water, that if there should be any foulness or sediment in it, on flushing it a little, it may all run through, and fresh water be put in its place; but this flushing the water need not be done more than once or twice in a winter, as there may be occasion from the foulness; and when this is done, the sides of the vessel should be cleaned with a painter's brush and rinsed out again, and the bulbs themselves washed, by pouring water on them at a little distance; and if any dull or foul matter be at any time observed swimming on the surface, the method is to fill up the vessel, and let it run over; this will carry off that light foulness, and the water may afterwards be poured away to the proper standard.

It may be more agreeable to some to use glass jars, in this last method with the lead, instead of earthen pots. The bulbs succeed full as well in these; and there is this advantage, that the progress of the roots is seen all the while, and they are managed better as to the supply of water.

By repeated experiments in this way on dried bulbs, and on those taken fresh out of the ground, the former have been found to succeed the best; for those taken fresh out of the ground being full of moisture, will not so soon upon changing their element be nourished fully by a new one; and the fibres which they had struck in the ground always rot when put into the water, and new ones must be formed in their places, so that it requires more time for them to come to *flowering*. The bulbs themselves will not rot in this manner, but they will never be so strong as those which were put into the water dry, which gradually fill themselves with moisture from it, and regularly plump up. The best method of managing the whole process is this: place the bulbs at first only on the surface of the water; for thus they will strike out their fibres most strongly. When they have stood thus six weeks, pour in the water to high as to cover them entirely, and keep them at this standard till they have done *flowering*.

Sometimes the roots will become mouldy in several parts while they stand above the water, and the cleaning them of it is in no purpose; for it will eat and spread the farther, and frequently eat through two or three of their coats. In this case, they must be immediately covered with water, and the mould will be stopped, and they will become sound, and *flower* as well as those which never had any such disfigurement. If the roots are suffered to remain in water all the year, they will not decay, but will *flower* again at their proper season, and thus as vigorously as those which are taken out and dried. The old fibres of those roots never rot till they are ready to push out new ones. It is found by experience, that the hyacinth, and many other plants, grow to greater perfection thus in water, than when in the ground. There is a peculiar species of hyacinth, called Keyser's jewel; this never, or however very rarely, produces seed-vessels in the common way of *flowering* in the ground.

but it will often produce some pods when blown in water.

Mr. Miller has intimated, in the Philosophical Transactions, that bulbs set in glasses grow weaker, and should be renewed with fresh ones every other year; but it is found that when they are managed in this manner, and kept under water, at the time of taking them up, they are as large, and some of them bigger and stronger than when planted; and if these be dried at a proper season, they will *flower* year after year as well as fresh ones.

The smaller sorts may also be raised in this manner, by the help of wool to support them.

No plant transplanted out of earth into water will thrive kindly; but any plant, whether raised from the root or seed in water, may be transplanted to the earth, and will succeed very well. It may be possible, therefore, from this method of raising plants in water, to come at a better way than is usually practised of raising some roots in the earth which are subject to rot there; such as anemones, ranunculuses, and hyacinths. A bulb dopped by chance upon the ground will strike out both stronger and more numerous fibres, than those which are planted in the usual way on the ground. On this principle it may be proper to take out the earth of the bed where the bulbs are to stand at the time of planting them, to such a depth as they are to be placed under it, when set for *flowering*. The bulbs are then to be set in their places on the surface of this low ground and to stand there till they have shot out their fibres and their roots; then the earth is to be added over them by degrees, till they are covered as high above the land as they are in the usual way of planting them; thus they would be preserved from the danger of rotting, and their fibres would be much stronger, and consequently they would draw more nourishment, and *flower* better than in the common way.

At the time of planting the bulbs, they must be carefully cleaned from any foulness at the bottom, by scraping them clean with the point of a knife, till the found part of the bulb appears clean then likewise from any loose thing, and even take off their brown skin, till they appear white; otherwise this brown skin will tinge the water, and the growth will not succeed so well.

There is yet another way of raising *flowers* to blow early in pots of earth in this manner. Dissolve crude sal ammoniac in water, in such proportion, as that a piece of the bigness of a walnut may be dissolved in every quart; then prepare some pots of a proper size, filled with good garden mould. Sow the annual *flowers*, and set the roots of the perennial ones, such as tulips, &c. in these pots at Michaelmas; continue the ensuing season to water them with the solution of the salt, and keep them in a warm room; by this means they will be in full flower about Christmas, and will continue through January and February.

FLOWING, or *Flows, flecti*, in Sea-Langage, denote the positions of the sheets, or lower corners of the principal sails, when they are loosened to the wind, so as to receive it into their cavities in a direction more usually perpendicular than when they are close-bowed, but more obliquely than when the vessel is sailing before the wind. This position of the sheets takes place when the wind crosses the line of her course nearly at right angles.

FLOX, in the Colour Trade, a very well cleaned wool used to absorb the colours of cochineal, &c. It is prepared in this manner: infuse a pound of the finest shavings of woollen cloth in cold water for one day; then take them up, and pers them well together, to wash off the unctuousity the wool naturally has. This is the simple *flox*, which when impregnated with a solution of alum, is called *aluned flox*. This is done in the following manner: take four ounces of rose-lind, and two ounces of crude tartar, both in fine powder; put them into an earthen vessel with three quarts of water, let it stew the fire, and when it begins to boil, then put in the *flox*; let the liquor now boil half an hour over a gentle fire, then take it off, and when all is perfectly cooled, wash the *flox* with fair water, letting them stand in it two hours, then press them in the hand, and let them dry.

FLUDER, or Sea-Fl. *tripda*, in Ornithology, the name of a water-fowl of the columbus or diver-kind, described by Geseaer, and some other authors, under the name of the columbus maximus, or largest diver. It is nearly of the size of a goose, and moves but very slowly on the water, and much worse either on land, or in the air, being but little able either to walk or fly. Its beak is long, and its legs very short; it makes a very shrill noise, and is remarkable for diving to vast depths. Its feet are webbed, its back is of a greyish colour, and its belly white. It seems much to approach to the northern columbus, called the lumme, and perhaps differs only in colour, which may be an accidental variety, as it is common in birds. Ray's Ornithol. p. 260.

MULLIN, *Elating*, in *Requy*. See **ELATIVE**.
MUENT, or *fewer quantity*, in the *Decl* of *Quant*, that quantity (whether *adj*, *noun*, *solid*, &c.) which is continually increasing or decreasing.
 Those *Quant*, which *inc* or *dec* in the same time, or in equal times, or which begin together and end together, are called *contemporary Quant* and their *Muents* are called *contemporary Muents* and if two or more of these *contemporary Muents* are always equal, or in any *intelligible* ratio to each other, their *contemporary Muents* will likewise be equal, or in the same proportion; and *viz* *ut* *q*. See **FLUXION**.

The Cartesian, and after him Dr. Hook, Mr. Boyle, be-
hinde the circumstances above mentioned, require a va-
rious, personal, distinct notion of the particles or
bodies, so that which principally contributes to *fluidity*,
fluidity then, according to these philosophers, consists in
this, that the parts of the body, being very fine, and
small, are so disposed by motion, or figure, as that they
can easily flow over one another's surfaces all manner of
ways, and so that they are not constant, various, separate
solidities, and free, and that they only touch one
another in some few parts of their surfaces. Mr. Boyle,
in his *lectures of Natural Philosophy*, mentions three conditions
principally required to *fluidity*, viz.

1. The minuteness of parts: thus, in effect, we find that fire, by dividing metals into fine, small parts, renders them fluid; and that acid menstrua dissolve and tender them fluid after the like manner; and that fire turns the hard body of common salt almost wholly into a li- quor, by distillation: not but that the figure of the particles may have a considerable share in fluidity.

Thus mercury, whose parts are doubtless much grosser than those of oil and water, is yet more fluid than either of them: and thus oil, by the action of fire, may be converted into a consistent substance like butter.

2. A number of vacancies interspersed between the corpuscles, to give room for the several particles to move among themselves.

3. A motion and agitation of the corpufcles; either from fome principle of mobility within themfelves, or from fome extraneous agent, penetrating and entering the pores, moving variously among them, and communicating to them a part of its motion.

That this law is the qualification chiefly required in *fluidity*, he argues from divers observations and experiments. Thus, a little dry powder of salablar, or plaster of Paris finely sifted, being put in a vessel over the fire, soon begins to boil like water; exhibiting all the motions and phenomena of a boiling liquor. It will tumble variously in great waves like that; will bear stirring with a stick as easily like that, without refluxing; nay, it strongly mixed near the side of the vessel, its waves will apparently dash against them: yet it is all the while a dry, parched powder.

The lake is covered in sand; a dish of which being set on a shrimp-head, briefly beaten by the sticks, or on the upper floor of a mill, it in all respects emulates the properties of a fluid body. A heavy body, e. g. will immediately sink in it to the bottom, and a light one emerge to the top. Each grain of sand has a constant vibratory and dancing motion; and if a hole be made in the side of the dish, the sand will run out like water.

That the parts of fluids are in continual motion, the

Cartesians bring divers considerations to prove it, 1. The transmutation of solid matter, as, ice into water, and vice versa; the solid substance of the body in those two states continuing the same, the parts, being fixed and at rest in the one, retain the touch; whereas in the other, being already in motion, they give way to the fluid motion.

Boerhaave places fire in the air, fire's being the first mover, and the carrier of life in other bodies, as air, water, &c. Without this, he shows that the atmosphere itself would fix into one solid mass. See FIAT and HEAT.

There is a difficulty, however, in accounting for the principle of life as very general fact, a difference from the amorphous, as not to come within the sphere of another's destruction. The fabric and constitution of our fluid body, water, it seems, that is hard to vary, and which has a great proportion of pores, or interstices vacant; so that matter, though not perfectly impermeable to the action of force, is altogether very generally and for a long time unchangeable, like Cement, and yet this fluid is easily reducible into that firm, transparent, friable body, which we call ice, by being first exposed to a certain degree of cold.

One would think, that though the particles of water cannot come near enough to attract each other, yet the interstices, tripping water dash, by being mingled per minima, strongly attract them, and is itself likewise strongly attracted by them, and so wedges of fire all the mass into a firm solid body; which solid body loses its solidity again, when by heat the vitium is solved, and the tripping particles are disjoined from those of the water, and are forced to fly out of it. And thus may the fumes of lead perhaps be quicksilver.

When a firm solid body, such as metal, is by heat reduced into a fluid, the particles of fire disjoin and separate into constituent parts, which their mutual attraction caused before to cohere, and keep them at such a distance from one another, as that they are out of the sphere of each other's attraction, as long as that violent motion lasts; and when by their ligaments and activities they are drawn off, unless they be renewed by a continual supply, the component particles of the metal finally come near enough again to feel one another's attractions.

As, therefore, the cause of cohesion of the parts of solid bodies appears to be their mutual attraction, to the chief cause of fluidity seems to be a contrary motion, impressed on the particles of fluids: by which they avoid and fly one another, as soon as they come at, and as long as they keep at such a distance from each other.

It is observed also in all fluids, that the direction of their pressure against the vessels which contain them is in lines, perpendicular to the sides of such vessel; which property, being the necessary result of the particles of any fluid's being spherical, shews that the parts of all fluids are so, or of a figure very nearly approaching thereto.

FLUIDS are bodies, whose particles are but weakly connected, their mutual cohesion being in a great measure prevented by some external cause.

In this Ionic a *fluid* stands in pos'd to a solid.
Sir I. Newton defines a *fluid* body, to be that whose
parts yield to the small it free impress'd, and by yield-
ing are easily moved among each other.

That the particles whereof fluids consist, are of the same nature, and have the same properties, with the particles of solids, is evident, from the conversion of liquids and solids into each other, e. g. of water into ice, of metals into flues, &c. Nor can it be reasonably doubted, that the component parts of all bodies are of the same, viz. last, solid, impenetrable, moveable, compact.

We observe they love, with Dr. Clarke, that if the parts of a body differ do not touch each other, or easily slide over one another, and are of such a magnitude, as that they may be easily agitated by heat, and the heat be sufficiently great to agitate them, though it may perhaps be less than sufficient to prevent water from freezing; or, even, though the parts be not actually moved, yet, if they be small, smooth, upper, and of such a figure and magnitude as dispose them to move, and give way, that body is fluid.

And yet the particles of such fluid bodies do, in some measure, cohere; as is evident hence, that mercury, when well purged of air, will be retained in the barometer, to the height of 60 or 70 inches; that water will ascend in capillary tubes even in vacuo; and that the drops of liquor in vacuum run into a spherical form; adhering by some mutual cohesion like that between polished marble planes. Add, that these fluid bodies, if they consist of particles that are easily entangled within each other, as oil, or if they be capable of being dissolved by cold, and joined by the interposition of little round or wedge, as water, they are easily considered hard; but if their particles be such as can neither be entangled, as air, nor dissolved by cold, as quicksilver; then they never grow hard and fixed.

Fluids are either *elementary*, as water, and mercury; or *mixed*, as blood, milk, bile, lymph, urine, &c. or *fictitious*, as wines, spirits, oils, &c. See each under its proper article.

The doctrine and laws of fluids are of the greatest extent in philosophy. The pressure and gravitation of bodies in fluids, and the action of the fluids immersed in them, make the subject of HYDROSTATICS.

Fluids, hydrostatical laws of. I. The upper parts of all fluids, as water, &c. are pressed upon the lower; or, as some philosophers state it, all fluids do gravitate in proportion.

The contrary of this was a principle in the school-philosophy; and two facts have been commonly urged in support of it. A bucket full of water is lighter in the water than out of it, nor does it weigh more when full in the water, than when empty out of it; therefore, it has been concluded, that the water in the bucket, because it is within water, its own element, does not gravitate; and divers who descended to considerable depths, it has been said, feel no sensible pressure under water; though at the depth of thirty-two feet, the additional pressure they sustain is not less than twenty thousand avoirdupois pounds; for, supposing the surface of the body to contain only ten square feet, and a cubic foot of water to weigh one thousand avoirdupois ounces, $10 \times 10 \times 10$, or $10 \times 10 \times 10$ feet of water will weigh 10×20000 avoirdupois ounces, or twenty thousand pounds. However, in this case, the uniformity of the pressure, the increased elasticity and resistance of the compressed internal air, and the firm texture of the membranes, &c. may prevent their complaining of any sensible pain; though there have been many instances to the contrary, in which the difference of the pressure has produced very injurious effects. See Diving.

As to the former fact, it is easily explained by the theory of specific gravity. The bucket of water weighs in water, but does not overweigh; because the surrounding parts of water condense in descent as well as the bucket, and with equal force, and therefore do not permit it to descend. Thus, according to an observation of Dr. Delisle, if two pound weights were hung at the two arms of a balance, no one will say, that neither weighs, because it does not outweigh the other. Delisle, Exp. Phil. vol. II. p. 66.

Before, it is evident, that in any fluid, the weight of the whole is equal to the weight of all its parts; and if any part be taken from the whole, the weight of the whole will be diminished by the weight of that part; and if any part be added to the whole, the weight of the whole will be increased by the weight of the part which was added; and, therefore, it is reasonable to conclude, that the weight of the whole is composed of the weights of the several parts, and that the parts do, therefore, gravitate in the whole, or in *proportion*. Coroll. Hyd. and Pneum. Lectures, p. 7. But the certainty of such pressure is now demonstrated by a thousand experiments: it will be sufficient to influence one or two.

Immerse a tube, open at both ends, and half filled with

oil of turpentine, in a vessel of water, the upper end of the tube being stopped with the finger; if now the upper surface of the oil be as low as that of the water, the oil, upon removing the finger, will not run out at the lower end of the tube; nay, and if the tube be thrust a little lower, the water will rise up in it, and bear the oil above it; but if the upper surface of the oil be considerably higher than that of the water, the oil will drop out of the tube. Whence it follows, that the column of oil in one case presses or gravitates less on the plane imagined to pass under its lower surface, than a column of water; and in the other case, more.

Or thus, a phial, with as much fluid in it as will make it sink, close shut, being immersed in water, and supported by a horse-hair to the beam of a balance, with a weight at the other end exactly counterpoising it; upon unloosening the phial, and letting it fill with water, it will preponderate, and bear down the end of the balance, without having any communication with the external air. And if the phial had been first weighed in air, it will be found, that the weights necessary for restoring its equilibrium in water, answer exactly to the additional weight of the phial, when it is again weighed in air with the water in it; so that water weighs in water just as much as in air.

These two experiments abundantly prove the proposition, that the upper parts of fluids do really press or gravitate on the lower. See SPECIFIC GRAVITY. From this gravity it follows, that the surfaces of stagnant fluids are plain, and parallel to the horizon; or rather, that they are segments of a sphere concentric with the earth, because they all gravitate towards the centre of the earth.

For, as the particles are supposed to yield to any force impressed, they will be moved by the action of gravity, till such time as some of them can descend any lower. And in this situation once attained, the fluid must remain at rest, unless put in motion by some foreign cause; inasmuch as none of the particles can now move without ascending, contrary to their natural tendency.

II. If a body be immersed in a fluid, either wholly, or in part, its lower surface will be pressed upwards by the water underneath it; and the pressure of fluids upwards is equal to the pressure downwards at the same depth.

The truth of this proposition is evident from the experiment above mentioned; where the oil of turpentine was suspended, and made to mount up in the tube, by the pressure of the water upwards on its lower parts. Thus also, if the open end of a narrow-bore tube be dipped into quicksilver, whilst the other end is stopped with the finger, and the tube be lifted up, a short column of quicksilver will be suspended in the lower end, which column, when dipped into water deeper than about fourteen times its own length, will be pressed upwards, after the finger is removed from the orifice.

This upward pressure of fluids may be evinced by causing a piece of lead, &c. to swim in water; which may be done by immersing it to a proper depth, and keeping the water from getting above it. Let CD, Tab. II. Hydrostatic, &c. 10. be a glass tube open at both ends, and EFG, a flat piece of lead half an inch thick, exactly fitted to the lower end of the tube, having its upper surface covered with wax leather, so as to hinder the entrance of the water contained in the outer vessel. Let this leaden plate be held close to the tube, by pulling the string or wire IHL upward at L with one hand, whilst the tube is held in the other by the upper end C. In this situation, let the tube be immersed in water in the glass vessel AB, to the depth of six inches below the surface of the water at K; and then, the leaden plate EFG will be plucked to the depth of four inches above the surface of the water; holding the tube at that depth, you may let go the wire or thread at L, and the lead will not fall from the tube, but will be kept to it by the upward pressure of the water below it, reckoned by the height of the water at K above the level of the lead. For, as lead is 11.33 times as heavy as its bulk of water, and in this experiment is immersed to a depth somewhat more than 11.33 times its thickness, and no water getting into the tube between it and the lead, the column of water E a b c G, below the lead, is pressed upward against it by the water KDEGL, all round the tube; which water, being a little more than 11.33 times as high as the lead is thick, is sufficient to balance and support the lead at the depth KE. If a little water be poured into the tube upon the lead, it will increase the weight upon the column of water under the lead, and cause the lead to fall from the tube to the bottom of the glass vessel, where it will lie in the situation b d; or, if the tube be raised a little in the water, the lead will fall by its own weight, which will then be too great for the pressure of the water

round the tube on the column of water below it. If the plate were brass instead of lead, it ought to be immersed under water to at least eight times its thickness, in order to be supported by the water; because brass is about eight times specifically heavier than water. A plate of pure gold would require near twenty times its thickness of water; and this led Mr. Boyle to propose one of his hydrostatic paradoxes in these words, viz. That a solid body, so ponderous as any yet known, though near the top of the water it will sink by its own weight, yet immersed in water, at a greater depth than that of twenty times its thickness, will not sink, if its descent be not assisted by the weight of the incumbent water. Paradox. 21. *Statics.* Boyle's Works, abridg'd by Shaw, vol. II. p. 311. As we have now seen that the heaviest body may be made to swim in water, the lightest wood may be made to lie at the bottom of water or mercury. Thus, let two pieces of wood be placed quite flat, so that no water may get between them when they are put together; let one of them, *b, d*, be cemented to the bottom of the vessel *A B*, fig. 10; and the other be laid flat and close upon it, and held down with a stick, whilst water is poured into the vessel; then remove the stick, and the upper piece of wood will not rise from the lower one, for as the upper one is pressed down both by its own weight and the weight of water over it, whilst the contrary pressure of the water is kept off by the wood under it, it will lie as still as the heaviest body; but if it be raised at the edge, so that the water may get under it, it will immediately be pressed upwards; and as it is lighter than its bulk of water, it will rise and float on the surface of the water. See Ferguson's Lectures, 4to. p. 68. and Notes to Hist. Lect. 2. See HYDROSTATIC BALLOON, and ART. XI. in the sequel.

The law or quantity of this pressure is this; that a body immersed in a fluid, loses just so much of the weight it would have in air, as so much of the fluid as is equal to it in bulk, is weighed in the air would amount to.

This pressure of fluids on the lower parts of an immersed body, is farther confirmed, by attending to the reason why bodies, specifically lighter than fluids, ascend therein. The effect is owing to this, that there is a greater pressure or weight on every other part of the plane or surface of the fluid imagined to pass under the lower surface of the body, than there is on that whereon the emerging body indents. Consequently, to produce an equilibrium in the fluid, the parts immediately under the rising body, being pressed by the rest every way, do continually force it upwards.

In effect, the emerging body is continually pressed on by two columns of water, one bearing against its upper and the other against its lower parts; the length of both which columns being to be accounted from the top of the water, that which presses on the lower part will be the longer, by the thickness of the ascending body, and consequently will overbalance it by the weight of as much water as will fill the space the body takes up. Hence, 1. We are furnished with one reason, why very minute corpuscles, either heavier or lighter than the liquor they are mingled with, will be sustained therein a good while, without either emerging to the top, or precipitating to the bottom; the difference between the two columns of the fluid being here inconsiderable.

Hence, 2. If a body *A* be specifically lighter than *B*, an equal portion of the fluid in which it is immersed, it will rise with a force proportionable to the excess of gravity of *B* above *A*; and if *A* be specifically heavier than *B*, it gravitates and descends with the excess only of its weight above that of *B*.

Hence, 3. We have a solution of the phenomenon of two polished marbles or other planes adhering so strongly together; because the atmosphere presses or gravitates with its whole weight on the under surface and sides of the lower marble, but cannot do so at all on its upper surface, which is closely contiguous to the upper and suspended marble.

III. The pressure of the upper parts of a fluid on the lower exerts itself every way, and every way equally, laterally, horizontally, and obliquely, as well as perpendicularly.

For, as the parts of a fluid yield to any impression, and are easily moved, it is impossible any drop should remain in its place, if, while it is pressed by the superincumbent fluid, it be not equally pressed on every side.

The same is confirmed from experiments: for several tubes of divers forms, thin, curved, angular, &c. being immersed in the same fluid, through the apertures, through which the fluid enters, be differently pointed to the surface or plane, some being perpendicular, others parallel, and others variously declined; yet will the fluid rise to an equal height in them all. See SYST. &c.

Hence, 1. All the particles of fluids being thus equally

pressed on all sides, it is argued, that they must be at rest, and not in continual motion, as has been usually supposed.

Hence, 2. also, A body, being immersed in a fluid, sustains a lateral pressure from the fluid, which is still increased as the body is placed deeper, inasmuch as the surface of the fluid.

IV. In tubes that have a communication with each other, whatever their magnitude be, when the fluid is horizontal; and wherever their form, whether fluid, regular, or crooked; still, fluid will in them rise to the same height.

V. If a fluid rise to the same altitude in two tubes that communicate with each other, the fluid in them is a balance, or equal in weight to that in the other.

If the tubes be of equal diameter, the columns of the fluid, having the same base and altitude, are equal, and consequently their gravities equal; so that they press and gravitate against each other with equal force.

This is demonstrated by experiments. E. g. Let the base of *G I*, *Tas. II. Fig. 12.* be supposed quadruple the base of *H K*; and let the fluid descend in the greater tube the space of an inch, as from *L* to *O*; it will then rise in the other the space of four inches, as from *M* to *N*. Wherefore the velocity wherewith the fluid moves in the tube *H K*, is to that wherewith it moves in *G I*, as the base of the tube *G I*, to the base of the other, *H K*. But the altitude of the fluid being supposed the same in both tubes, the quantity of the fluid in the tube *G I* will be to that in the other tube *H K*, as the base of the tube *G I* to the base of the other *H K*.

Consequently, the momentum of the fluid in the tube *G I* is to that in the tube *H K*, as the product of the base of the tube *G I* into the base of the other *H K*, to the factum of the tube *H K* into the base of the other *G I*. Wherefore, the products being equal, the momenta must be equal.

The same is easily demonstrated where one of the tubes is inclined, and the other perpendicular, &c.

Hence in tubes that communicate, the fluid will preponderate in that where its altitude is the greatest.

VI. In communicating tubes, fluids of different specific gravities will equiponderate; if their altitudes be in the ratio of their specific gravities.

Hence we have a way of finding the specific gravities of fluids, viz. by pouring one fluid into one of the communicating tubes, as *AB* (fig. 12.) and another into the other tube *CD*; and measuring the altitudes *GB* and *HD*, at which they stand when balanced.

For the specific gravity of the fluid in *AB* is to that in *DC*, as *DH* to *BG*. If the fluids employed in this experiment be apt to mix, it may be proper to fill the horizontal tube *BD* with mercury, to prevent the mixture. Hence, since the densities of fluids are as their specific gravities, the densities will likewise be as the altitudes of the fluid *DH* and *BG*; so that we have hence likewise a method of determining the densities of fluids.

VII. The bottoms and sides of vessels are pressed in the same manner, and by the same laws, as the liquids contained in them.

And hence, as action and reaction are equal, the fluids themselves sustain an equal pressure from the bottoms and sides. And as the pressure of fluids is equal every way, the bottoms and sides are pressed as much as the neighbouring parts of the fluids; and consequently this action increases in proportion to the height of the fluid, and is equal every way at the same depth; as depending altogether on the height, and not at all on the quantity of the fluid.

VIII. In perpendicular vessels of equal bases, the pressure of fluids on the bottoms is in the ratio of their altitudes. This is evident, because, the vessels being perpendicular, the bottoms are horizontal; consequently the tendency of fluids by the action of gravity will be in lines perpendicular to the bottoms, so that they will press with all their weight; the bottoms therefore are pressed in the ratio of the gravities. But the gravities are as the bulks, and the bulks here are as the altitudes; therefore the pressure on the bottoms are as the altitudes.

IX. In perpendicular vessels of unequal bases, the pressure on the bottoms is in a ratio compounded of the bases, and altitudes.

From the preceding demonstration it appears, that the bottoms are pressed in the ratio of the gravities; and the gravities of fluids are as their bulks; and their bulks in a ratio compounded of the bases and altitudes. Consequently, &c.

X. If an inclined vessel *ABCD*, fig. 13. have the same base and altitude with a perpendicular one, *BEFG*, the bottoms of each will be equally pressed.

For, in the inclined vessel *ABCD*, the bottom *CD* is pressed in the direction *BD*. But the force of gravity in the direction *BD* is to the absolute gravity, as *BE* to *BD*.

Conse-

Consequently, the bottom CD is pressed in the same manner, as if it had been pressed perpendicularly by the fluid under the altitude BL. Therefore, the bottoms of the perpendicular and inclined vessels are equally pressed.

XI. *Fluids press upon subject bodies, according to their perpendicular altitude, and not according to their latitude, or breadth.*

Or, *whereas fluid is, thus, if a vessel be taper, or unequally digged up and bottom, yet the bottom will be pressed after the same manner, as if the vessel were cylindrical, and the top and bottom equal.*

Or, *thus, the pressure, sustained by the bottom of a vessel, whatever the figure of the vessel be, is ever equal to the weight of a column of the fluid, whose base is the bottom itself, and whose vertical distance of the upper surface of the water from the bottom.*

Or, *yet more explicitly, that: if there be two tubes or vessels, having the same heights, and bases, both filled with water; but one of them made to taper upwards, that it shall contain but twenty ounces of water; whereas the other, widening upwards, holds two hundred ounces; yet the bottoms of the two tubes shall sustain an equal pressure of water, viz. each of them that of the weight of two hundred ounces.*

This is a noble paradox in hydrostatics, first discovered by M. Pascal, and which it is well worth the clearing and settling on. It is found unexpectedly true from abundant experiments; and it may even be demonstrated and accounted for on principles of mechanics.

Suppose, e. g. the bottom of a vessel CD (fig. 13) less than its top AB, since the fluid under the bottom CD, which we suppose horizontal, in a perpendicular direction, EC, were but that part within the cylinder ECDF can press upon it, the natural tendency and pressure of the rest being taken off by the sides.

Again, supposing the bottom CD (fig. 15.) much bigger than the top FG; or, even, for the easier demonstration, suppose a tube FE fixed in a cylinder ABCD; and suppose the bottom CD raised to L, that the fluid may be moved through the interval DL, then will it have risen through the altitude GL, which is as DL as the base CD to that of GF. The velocity therefore of the fluid FE is to its velocity in the vessel AD as the base CD to the base FG.

Hence we have the momentum wherewith the fluid in the tube tends downwards, by multiplying the base of the cylinder CD into its altitude GL.

Consequently, the bottom CD is pressed with the same force, as it would be pressed by the cylinder ECDF. To confirm and illustrate this doctrine of the pressure of fluids in the ratio of the base and altitude, provide a metallic vessel ACDB (fig. 14.) contrived, so that the bottom CD may be movable, and so that end fitted in the cavity of the vessel with a rim of wet leather, to slide freely without letting any water pass. For this purpose it would be most advisable, that the movable bottom should have a groove round its edge, and that it be put into a bladder, tied close round it in the groove by a strong waxen thread; and the bladder may be made to come up like a purse within the vessel, and put over the top of it at A and B all round, and then the lid of the vessel pressed on it: so that when water is poured through a hole in the lid, it would lie upon the bottom CD, and be contained within the bladder. Then, through holes in the top, AB, apply successively several tubs of equal altitudes, but of different diameters. Lastly, fastening a string or wire to the beam of a balance, and fixing the other end by a little ring K to the movable bottom, put weights in the other scale, till they be sufficient to raise the bottom CD: then will you not only find, that the same weight is required, what diameter or magnitude of vessel the tube is of; but even, that the weight which will raise the bottom when pressed by the smallest tube, will raise it when pressed by the whole cylinder ECDF.

Suppose the vessel ABCD to hold about a pound of water, and that the movable bottom, wire, and hook, are of equal weight with an empty scale M. When this scale is pulled down, the bottom CD will be drawn up within the box, and that motion will cause the water to rise in the glass tube ELYG. If one pound be put into the scale, the bottom will be moved a little, and the water will fall appear at the lower end of the tube at *a*. Another pound will cause it to rise from *a* to *b*, just twice as high above the bottom as it was when at *a*; the pressure on the bottom being equal to two pounds, the counterbalancing weight in the scale M. A third pound will raise it to *c*, a fourth to *d*, &c. the distances *a*, *b*, *c*, *d*, &c. being taken equal to each other and to the depth of the vessel. If another tube, *xy*, be put into a hole made in the top of the vessel, and the vessel be filled with water; and, then, if a water be poured in at the top of the tube FGEL, it will rise in the tube *xy* to the same height

as it does in the other tube: from hence it is evident, that the upward pressure of the water, rising in the tube *xy*, is equal to the downward pressure in the other tube FGEL: the cause would be the same, whatever be the number of tubes; and the movable bottom would sustain the weight of the water in all the tubes, besides the weight of all the water in the vessel; and if all the holes to which these tubes (FGEL excepted) were fixed be stopped up, each part, thus stopped, will be pressed upward with a force equal to the weight of water in each tube; and, consequently, the whole upward pressure against the top of the vessel, arising from the weight or downward pressure of the water in the tube FGEL, will be equal to the weight of a column of water of the same height with that in the tube, and of the same thickness as the width of the inside of the box or of the movable bottom; and this upward pressure against the top will reach downwards with equal force against the bottom.

If the diameter of the movable bottom be three inches, therefore, and the diameter of the bore of the tube a quarter of an inch, their squares will be nine inches and one sixteenth of an inch; and therefore the whole area of the bottom will be a hundred and forty-four times as great as that of the area of the bottom or top of the tube; so that if the movable bottom be raised one inch, the water would be raised to the top of a tube a hundred and forty-four inches, or twelve feet in height. The vessel must be open below the movable bottom to let in the air, otherwise the pressure of the atmosphere upon it, opposing its descent three inches, would require a counterbalance of a hundred and eight pounds in the scale M before the bottom would begin to move. See *HYDROSTATIC DESIGN*.

XII. From the preceding articles, we may easily deduce a method of, estimating the quantity of pressure of fluids on any given surface. Let *abc* (fig. 16.) represent a cubical vessel full of water; the side *ac* will, therefore, represent a square; and the measure of the pressure on every physical point of *ac* will be the altitude of the water above that point; thus, the pressure on *i* is measured by *ei*, on *m* by *am*, &c. and the pressure on the whole line will be measured by the sum of as many altitudes *a*, *i*, *m*, &c. as there are points in the line *ac*. Erect perpendiculars *ls*, *ny*, &c. respectively equal to *ei*, *am*, &c. and the sum of these perpendiculars will be the measure of the whole pressure on the line *ac*; but the sum of these is equal to the area of the triangle *acd*; and this is as the square of its altitude *ac*. When *ac* represents a square, the triangle *acd* must represent a prism, having the said triangle for its base, and the side of the square for its altitude: the weight of this prism of water is, therefore, equal to the pressure made against the square, or side of the cube; which, as the prism is half the cube, is equal to half the weight of the whole water contained in the vessel; and as each side bears the same degree of pressure, all the four sides sustain four times half the weight, or twice the whole weight of the water; and because the bottom sustains a pressure equal to the whole weight of the water, the bottom and sides of a cubical vessel taken together sustain a pressure from the water contained in it equal to three times its weight. The same observations may be easily applied to planes that are oblique to the horizon, and we may conclude universally, that the pressure upon any plane, of whatever figure and situation, is equivalent to the weight of a solid of water, formed by erecting perpendiculars upon every point of the plane projected, equal to the respective distances of these points from the upper surface of the water; or, the pressure on any surface is equal to the sum of all the products which are made by multiplying every indefinitely small part of the surface into its distance from the top of the water. To find the sum of all these products, or a body of water equal to that sum, is, in most cases, a difficult problem: *Simon Stevin* has attempted the solution of it in few instances, confining himself to regular plain surfaces. Mr. *Cotes* has laid down the following universal and expeditious rule: the pressure on any surface is equal to the weight of a body of water whose magnitude is found by multiplying the surface proposed into the depth of its centre of gravity under water; and the pressure on any number of surfaces of different bodies, however differently situated, is equal to the weight of a body of water whose magnitude is found by multiplying the sum of all those surfaces into the depth of their common centre of gravity under water. The demonstration of this rule depends on the following theorem, viz. that the sum of the products, arising from multiplying every indefinitely small part of any surface, or number of surfaces, respectively, into its perpendicular distance from any proposed plane, will be equal to the product of the whole surface or number of surfaces multiplied into the perpendicular distance of the centre

of gravity of any single surface, or of the common centre of gravity of the whole number of surfaces from the same plane. Thus, let a, b, c, d (fig. 17.) represent weights, hanging at their centres of gravity, a, b, c, d , by the lines aa', bb', cc', dd' , fixed to a horizontal plane e, a, b, c, d , and let e be the common centre of gravity of all the weights, and no its perpendicular distance from the said plane. Let z be the common centre of gravity of a and b , and z to no , drawn parallel to the said, let am and bn be perpendicular. In the similar triangles amz and bnz , $am:bn::az:bz::a:b$. See CENTRE OF GRAVITY. Therefore $amx+bnx=bx+ax$, i. e. $amx+bnx=bx+ax$, and, consequently, $amx+bnx=bx+ax$. In the common centre of gravity of a and b found a weight $x=a+b$, and a weight $y=x+z$ in the common centre of gravity of x and c , and a weight $z=y+d$, in the common centre of gravity of y and d . Then z is the common centre of gravity of a, b, c, d . And we have (as above) $amx+bnx=bx+ax$, and $amx+bnx=yx$, and $yx+z=dz$, and $yx+z=xz$; consequently $amx+bnx+dx+cx=dx+cx$; and this will be the case, if the perpendicular no , &c. be perpendicular to any plane, though not parallel to the horizon. Now taking the superficies of water for that plane to which we refer the indefinitely small parts of the surface which is exposed to the pressure we are concerned with; since it has been already shown, that the pressure upon the whole is equivalent to the weight of a body of water which is equal in magnitude to the sum of all the products, made by multiplying every little part by its distance from the upper plane of the water; and that this sum of products is exactly equal to the product of the whole surface or number of surfaces multiplied into the distance of the centre of gravity from the upper plane of the water; it will follow, that the same product is the measure of a magnitude of water, whose weight is equivalent to the pressure required. See COUL'S Hydrof. Lect. 3.

For the laws of the pressure and gravitation in FLUIDS specifically heavier, or lighter, than the bodies immersed, see GRAVITY, Specific.

For the laws of the resistance of FLUIDS, or the retardation of solid bodies moving in fluids, see RESISTANCE. For the ascent of FLUIDS in capillary tubes, or between glass plates, see ASCENT and CAPILLARY TUBES.

The motions of fluids, and particularly water, do also make the subject of hydrostatics.

FLUIDS, Hydraulic Laws of. I. The velocity of a fluid, as water, moved by the pressure of a superincumbent fluid, as air, is equal at equal depths, and unequal at unequal ones.

For the pressure being equal at equal depths, the velocity arising thence must be too; and vice versa: yet the velocity does not follow the same proportion as the depth, notwithstanding that the pressure, whence the velocity arises, does increase in the proportion of the depth. But here the quantity of the matter is concerned: and the quantity of motion, which is compounded of the ratio of the velocity and quantity of matter, is increased in equal times as the square of the velocities.

II. The velocity of a fluid arising from the pressure of a superincumbent fluid, at any depth, is the same as that which a body would acquire in falling from a height equal to the depth; as is demonstrated both from mechanics and experiments. See DESCENT.

III. If two tubes of equal diameters, full of any fluid, be placed in any position, either erect, or inclined; provided they be of the same altitude, they will discharge equal quantities of the fluid in equal times.

That tubes, every way equal, discharging under the same circumstances, empty themselves equally, is evident; and that the bottom of a perpendicular tube is pressed with the same force, as that of an inclined one, when their altitudes are equal, has already been shown. Whence it easily follows, that they must yield equal quantities of water, &c.

IV. If two tubes of equal altitudes, but of unequal apertures, be kept constantly full of water, the quantities of water they yield in the same time, will be as the diameters; and this, whether they be erect, or any way inclined.

Hence, if the apertures be circular, the quantities of water emptied in the same time, ought to be in a duplicate ratio of the diameters.

But this law, Mariotte observes, is not perfectly agreeable to experiment. If one diameter be double the other, the water flowing out of the less is found more than a fourth of what flows out of the greater. But this may have been owing to some accidental irregularities in making the experiments.

Wolffius however ascribes it principally to this, that the

column of water directly over the aperture is flatter than that next the sides or parietes of the vessel. For the water, in its efflux, forms a kind of cavity over the aperture; that part immediately over it being depressed first, and the other water not running fast enough from the sides to supply it. Now, this cavity, or diminution of altitude, being greater in the greater tube, than in the less; hence the pressure, or endeavour to push out, becomes proportionally less in the greater tube, than in the less.

V. If the apertures E and F (fig. 18.) of the vessels AB and CD (fig. 18. and 19.) be equal, the quantities of water, discharged in the same time, will be as the altitudes.

VI. If two tubes have equal apertures E and F , and unequal altitudes AB and CD , the quantity of water discharged from the greater AB shall be to that discharged from CD , in the same time, as the subduplicate ratio of the altitudes AB and CD .

Hence, 1. The altitudes of tubes AB , and CD , discharged through equal apertures E and F , will be in a duplicate ratio of the water discharged in the same time. And as the quantities of water are as the velocities, the velocities are likewise in a subduplicate ratio of their altitudes.

Hence, 2. The ratio of the waters discharged by two tubes AB , and CD , together with the altitude of one of them, being given, we have a method of finding the altitude of the other, viz. by finding a fourth proportional to the three given quantities, which, proportional, multiplied by itself, gives the altitude of CD , required.

Hence, also, 3. The ratio of the altitudes of two tubes of equal apertures being given, as also the quantity of water discharged by one of them, we have a method of determining the quantity the other should discharge in the same time.

Thus, to the given altitudes, and the square of the quantity of water discharged at one aperture, find a fourth proportional. The square root of this will be the quantity of water required.

Suppose, e. gr. the height of the tubes as 9 to 25, and the quantity of water discharged at one of them, three inches; that discharged by the other will be $=\sqrt{9 \times 25} = 15$ inches.

VII. If the altitude of two tubes AB and CD be unequal, and the apertures E and F be likewise unequal, the quantities of water, discharged in the same time, will be in a ratio compounded of the simple ratio of the apertures, and the subduplicate one of the altitudes.

And hence, if the quantities of water discharged in the same time by two tubes, whose apertures and altitudes are unequal, be equal, the apertures are reciprocally as the roots of the altitudes, and the altitudes in a reciprocal ratio of the squares of the apertures.

VIII. If the altitudes of two tubes be equal, the water will flow out with equal velocity, however unequal the apertures be.

IX. If the altitudes of two tubes AB and CD , as also their apertures E and F , be unequal, the velocities of the waters discharged are in a subduplicate ratio of their altitudes.

And hence, 1. As the velocities of waters flowing out at equal apertures, when the altitudes are unequal, are also in a subduplicate ratio of the altitudes, and as this ratio is equal if the altitudes be equal, it appears in the general, that the velocities of waters flowing out of tubes, are in a subduplicate ratio of their altitudes.

Hence also, 2. The squares of the velocities are as the altitudes.

Mariotte found, from repeated experiments, that if a vessel $ABCD$ have a tube EG fitted to it, there will more water be evacuated through the tube, than there could have been, in the same time, through the aperture of the vessel E without the tube; and that the motion of the fluid is accelerated so much the more, as the tube EG is the longer.

E. gr. The altitude of a vessel AC being one foot, that of the tube EG three feet, and the diameter of the aperture three lines, no less than 64 septiers of water were discharged in the space of one minute; whereas, upon taking off the tube, only four septiers were discharged. Again, when the length of the tube EG was six feet, and the diameter of the aperture 8 in inch, the whole quantity of water run out in thirty-seven seconds; but cutting off half the tube, the vessel was not evacuated in less than forty-five seconds; and, taking it quite away, in less than ninety-five seconds.

X. The altitudes and apertures of two cylinders full of water being the same, one of them will discharge double the quantity of water discharged in the same time by the other, if the first be kept constantly full, while the other runs itself empty; for the velocity of the full vessel will be equal, and that of the other will be continually

nally retarded. Now it is demonstrated, that, if two bodies be impelled by the same force, and the one proceeds equally, and the second is equally retarded, by that time they have lost all their motion, the one has moved double the space of the other.

XI. If two tubes have the same altitudes, and equal apertures, the times wherein they will empty themselves, will be in the ratio of their bases.

XII. Cylindric and grismatic vessels, as ABCD (fig. 20.) empty themselves by this law, that the quantities of water discharged in equal times decrease, according to the uneven numbers, 1, 3, 5, 7, 9, &c. taken backwards.

For the velocity of the descending level FG is continually decreasing in the subduplicate ratio of the decreasing altitudes; but the velocity of a heavy body descending, increases in the subduplicate ratio of the increasing altitudes. The motion, therefore, of the level FG, in its descent from G to B, is the same as if it were to descend in the inverse ratio from B to G; but, if it descend from B to G, the spaces, in equal times, would increase, according to the progression of the uneven numbers; consequently the altitudes of the level FG, in equal times, would decrease, according to the same progression inversely taken.

Hence, therefore, the level of water EG descends by the same law, as, by an equal force impressed, it would ascend through an altitude equal to BG.

From this principle, many other particular laws of the motion of fluids might be demonstrated, which, for brevity sake, we here omit.

To divide a cylindrical vessel into parts, which shall be evacuated in certain parts or divisions of time, see CLAUDIUS.

XIII. If water descending through a tube HE (fig. 21.) spout up at the aperture G, whose direction is vertical, it will rise to the same altitude GI, at which the level of the water LM, in the vessel ABCD, does stand.

For since the water is driven through the aperture G by the force of gravity of the column EK, its velocity will be same as that with which a body, by the same force impressed, would rise to the altitude GI: wherefore, since the direction of the aperture is vertical, the direction of the water spouting through it, will be so too; consequently the water will rise to the height of the level of the water LM in the vessel.

Indeed, by the experiment, it appears, that the water does not rise quite so high as I: besides, the aperture G should be smaller, as the height of the level of the water is less; and even smaller when mercury is to be spouted than when water. But this is no objection to the truth of the theorem; it only shows, that there are certain external impediments, which diminish the ascent. Such are, the resistance of air, and the friction of the tube, &c. See JET d'EAU.

XIV. Water, descending through an inclined tube, or a tube bent in any manner, will spout up, through a perpendicular aperture, to the height of which the level of the water in the vessel stands.

XV. The lengths or distances DE and DF, or IH and IG, (fig. 22.) to which water will spout either through an inclined, or an horizontal aperture D, are in a subduplicate ratio of the altitudes in the vessel, or tube AB and AC.

For since water, spouted out through the aperture D, endeavours to proceed in the horizontal line DE, and, at the same time, by the power of gravity, tends downwards in lines perpendicular to the same; not so the one power hinder the other, inasmuch as the directions are not contrary; it follows, that the water, by the direction BA, will arrive at the line IG in the same time wherein it would have arrived at it, had there been no horizontal impulse at all. Now, the right lines IH and IG are the spaces which the same water would have described in the mean time by the horizontal impulse; but the spaces IH and IG, inasmuch as the motion is uniform, are as the velocities: consequently the velocities are in a subduplicate ratio of the altitudes AB and AC; and therefore the lengths or distances, to which the water will spout in apertures either horizontal or inclined, are in a subduplicate ratio of the altitudes.

That the velocities are in the subduplicate ratio of the altitudes may be shewn by experiment: for, let two pipes as C and g, of equal diameters, be fixed into the side of the vessel AB, (fig. 23.) and let the pipe g be four times as deep below the surface of the water as i, in the vessel, as the pipe C is; and whilst these pipes run, let the water be constantly poured into the vessel, to keep the surface at the same height. Then a vessel holding a pint, applied to the spout g, will be filled at the same time. The horizontal distance, to which a fluid will spout from an horizontal pipe, in any part of the side

of an upright vessel, below the surface of the fluid, is equal to twice the length of a perpendicular to the side of the vessel, drawn from the mouth of the pipe to a semicircle described upon the altitude of the fluid; and therefore, the fluid will spout to the greatest distance possible from a pipe, whose mouth is at the centre of the semicircle; because a perpendicular to its diameter (supposed parallel to the side of the vessel) drawn from that point, is the longest that can possibly be drawn from any part of the diameter to the circumference of the semicircle. Thus, if the vessel AB, fig. 23. be full of water, the horizontal pipe D be in the middle of its side, and the semicircle N d e h be described on D as a centre, with the radius D N, or D h, the perpendicular D d to the diameter D N h is the longest that can be drawn from any part of the diameter to the circumference N d e h. And if the vessel be kept full, the jet G will spout from the pipe D to the horizontal distance N M, which is double the length of the perpendicular D d. If two other pipes, as C and E, be fixed into the side of the vessel at equal distances above and below the pipe D, the perpendiculars C e and E e, from these pipes to the semicircle, will be equal; and the jets F and H, spouting from them, will each go to the horizontal distance N K, which is double the length of either of the equal perpendiculars C e or E e. Ferguison's LEÇ. p. 70.

Hence, as every body, projected either horizontally or obliquely, in an unresisting medium, describes a parabola, water projected either through a vertical or inclined spout, will describe a parabola.

Hence we have a way of making a delightful kind of water arbours, or arches, viz. by placing several inclined tubes in the same right line.

On these principles are turned various hydraulic engines for the raising, &c. of fluids, as pumps, syphons, fountains, or jets d'eau, &c. which see described under their proper articles PUMP, SYPHON, FOUNTAIN, SPIRAL, SCREW, &c.

For the laws of the motion of FLUIDS, by their own gravity, along open channels, &c. see RIVER, and WAVE, and Motion of WATER.

For the laws of pressure and motion of air, considered as a FLUID, see AIR, and WIND.

FLUIDS. Animals called in fluids are of divers kinds; some are flat, others eel-kind, but the greater part of an oval figure. Leewenhoek gives a description of a very unusual shaped creature, fixed in a little leahard or death, which was fastened to some of the small green weeds found in ditches full of water. Phil. Trans. No 377. p. 160.

Waters of all kinds, that have stood a while exposed to the air, till they have grown a little putrid, or where putrefaction has been promoted by the admixture of other waters, abound in variety of animalcules, having each their peculiar characters, sizes, figures, economy, and method of life, not to say life. In a small drop of the discoloured surface of rain-water, which had stood two months in a window, Dr. Harris observed four sorts of animalcules: the clear part of the drop presented two kinds, both very small; the fill of the figure of ants; these were in a continual brisk motion. The second more oblong, three times as long as broad, were exceedingly numerous, but their motion slow.

In the thick part of the drop there were also two sorts of animalcules. The first of the eel-kind, resembling those in vinegar, but much smaller, and with their extremities more sharp. These would wriggle out into the clear part, and then suddenly betake themselves back again, and hide in the thick and muddy part of the drop, much like common eels in the water. The second sort resembled a large maggot, which would contract themselves into a spherical figure, and then stretch out again. The end of the tail appeared with a forceps, like that of an ear-wig. They might be plainly perceived to open and shut their mouths, from whence air-bubbles were frequently discharged. The number of these was not above four or five. The same four kinds of animalcules he also found in many other drops of the same corrupted water. Animalcules in fluids are generally found at the top. In the lower parts of the water, Dr. Harris assures us he could never find any, unless when the liquor had been disturbed, and the surface shaken down, and mingled with the lower parts. Dr. Harris examined some rain-water that had stood uncovered a little while, but had not contracted any thick or discoloured cum.

And here, where the water was clear, he could not find any animals at all; but a little thin white cum, that, like grease, began to appear in its surface, he found to be a congeries of exceeding small animals of different shapes and sizes, much like those produced by sleeping barley in water.

Viewing a small drop of the green surface of some piddle

water, he found it altogether composed of animalcules of several shapes and magnitudes; the most remarkable were those which gave the water that green colour, and were oval creatures, whose middle part were of a greenish, but each clear and transparent. They could contract and dilate themselves, tumble over and over many times together, and then shoot away like fishes. Phil. Trans. N° 220, p. 235.

Dr. Harris looked on the infusions of some mineral chalybeate water, which stood in a vessel unstoppered for about three weeks. In it he saw two kinds of animals, one exceeding small, and the other very large, which latter first had on the tail something that looked like hair. There were but very few of either kind. Phil. Trans. N° 230, p. 257, seq.

Animalcules in fluids are easily destroyed by only separating them a while from their element. Naturalists have even found shorter ways. A needle-point dipped in spirit of vitriol, and then plunged into a drop of pepper-water, readily kills all the animalcules, which, though before living about with great vivacity and activity, no longer come within the influence of the acid particles, than they found themselves, and tumble down to all appearance dead. The like may be done by a solution of salt, only with this difference; that by the application of this latter, they seem to grow vermiciform, turning round and round, till they fall down. The figure of salt is rather odd in the same manner kills them still more readily; yet not so, but there will be apparent marks of their being sick first and convulsed. To destroy them as fast as spirit of vitriol, and human blood, by virtue of the salt contained in it, produces the same effect. Dimes, fads, and sugar, do all destroy them, though not so fast; besides, that there is some diversity in their figures and appearances, as they receive their deaths from this poison, or that. The point of a pin dipped in puddle recently killed all the kinds of animalcules in puddle water, as Dr. Harris supposes it will other animalcules of this kind. Phil. Trans. N° 203, p. 263, seq. and N° 270, p. 276.

We find in the waters of our ditches many species of small animalcules, both of the crustaceous and testaceous kinds. The legs of the crustaceous are short, they resemble those of crabs and lobsters, but are of a much more curious structure; they are less than a small flea, but they have all members, carrying spurs at their tails, or in two small legs, one hanging from each side. Their legs are often broken, and the spurs are then found to consist of globules very large in proportion to the size of the creature. There is another sort beside these, as beautiful, but much smaller than they; this in form more resembles the shrimp, and carries its spurs as the shrimp does. Their tails both form only to have one eye, and that placed exactly in the middle of their forehead, without the least trace of a dividing line; and they are often so transparent, that the motion of their bowels, and pulsation of their heart, may be seen. Baker's Microscope, p. 93.

All who are acquainted with the microscope, know very well, that in water, in which the best glasses can discover no animated particles of matter, after a few grains of pepper, or a small fragment of a plant of almost any kind, has been some time in it, animals full of life and motion are produced, and those so numerous as to equal the fluid itself in quantity.

A small quantity of water taken from any ditch in the summer months, is found to be full of little worms, seeming in nothing to much as far to differ from their microscopic animalcules. Nay water, without these, exposed in open vessels in the summer months, will be always found, after a few days, to abound with multitudes of them, visible to the naked eye, and full of life and motion.

That we know, by their future changes, are the fly-worms of the different species of gnats, pupae, and multitudes of the other fly-species, and we can easily determine, that they have owed their origin only to the eggs of the parent fly there deposited. Now, a closer observation will at any time give us a proof of this; as the flies may be seen laying their eggs there, and those eggs may be followed in all their changes to the fly again. Why then are we to doubt but that the air abounds with other flies and animalcules, as minute as the worms in their state; and that these last are only the fly-worms of the former, which alter a proper time spent in that state, will suffer changes like those of the larger kind, and become flies like those to whose eggs they owed their origin? Vide Reaumur, Hist. Insect. vol. iv. p. 271.

The differently mediated liquors, made by the infusions of different plants, afford a proper matter for the worms of different species of these small flies; and there is no reason to doubt but among these some are viviparous,

others oviparous, and to this may be in a great measure owing the different time taken up in the production of the insects in different fluids. Those which are a proper matter for the worms of the viviparous flies may be soonest found full of them, as probably the nature is no sooner in a state to afford them a proper nutriment than their parents place them there; whereas those produced from the eggs of the little oviparous flies must wait till the liquor is in a proper state, and they are deposited in it, in form of eggs, have a proper time to be hatched before they can appear alive.

It is easy to prove that the same air as these vegetable infusions were brought out from some other place. It is not less easy to show that it could not be in the matter-infused, any more than the fluid it is infused in.

Notwithstanding the freedom of growth of filarimanders, it is now well known that animal, large or small, can bear the heat of a great deal of time, and by parity of reason we may believe, that any insect, or curious infusible in any way, can bear the heat of boiling water for many minutes. To proceed to enquiries on that foundation, if several tubes filled with water with a small quantity of vegetable matter, such as pepper, oak-bark, truffles, &c. in which, after a time, insects will be discovered by the microscope, and other like tubes be filled with simple water boiled, with water and pepper boiled together, and with water with the two other ingredients, all separately boiled in it; when all these liquors come to a proper time for the observation of the microscope, all, as well those which have been boiled as those which have not, will be found equally to abound with insects, and those of the same kind in the infusions of the same kind, whether boiled or not boiled.

Those in the infusions which had sustained a heat capable of destroying animal life, must therefore not have fulfilled either in the water, or in the matter put into it, but must have been brought thither, after boiling, and it seems by no way to be probable, as by means of some little winged inhabitants of the air depositing their eggs or worms in those fluids.

It is a natural question on this to ask, why it is, that while we see myriads of the progeny of these winged insects in water, we seldom for the insects themselves? The answer is equally easy, viz. because we can always place a drop of this water immediately before the focus of the microscope, and keep it there while we at leisure examine its contents; but that is not the case with regard to the air inhabited by the parent flies of these our worms, which is of immense extent in proportion to the water proper to nourish these worms, and consequently, while the latter are clustered together in heaps, the former may be dispersed and scattered. Nor do we want instances of this even in the insects of a larger kind. In many of our gardens we frequently find vessels of water filled with the great-worms, as plentifully in proportion to their size, as these our fluid with animalcules. Every cubic inch of water in these vessels contains many hundreds of these animals; yet we see many cubic inches of the air in the garden not affording any one of the parent flies. Id. ibid. See ANIMALCULES, EEL, VIKAR, and PEPPER-WATER.

FLUID, *Caustic*. See CAUSTIC-FLUID.

FLUID, *Serious*. See SERIOUS-FLUID.

FLUKE, in *Lithology*, a word used in some parts of England as a name for the PLOWORK.

FLUKE of an anchor, that part of it which falls in the ground. See ANCHOR.

FLUKEN, in *Natural History*, a name given by the miners in Cornwall, and some other places, to a sort of greyish soft-earth, in which there are a great number of small white bones of a stony nature. They usually find this most substance near the places where the loads or veins of ore lie, and it seems evidently to have been washed from among the broken parts of the strata near where the metals lie. It is itself a coarse and often soft earth, and the white bones which it contains, are sometimes small crystalline, but opaque pebbles, of the nature of those which we find of various sizes in our sand and gravel-pits; but more usually they are small fragments of common spar, and are of a splined figure when broken, and seem only rounded by the motion of the water, like many small stones which are found in the beds of rivers, and on the sea-shores. The soft nature of the substance of which these are composed makes them easily liable to be robbed into a round figure.

FLUMMERY, a wholesome sort of vegetable jelly made of carmel.

The manner of preparing it is as follows: put in the proportion of three large handfuls of finely ground oatmeal, to steep for twenty-four hours or more, in two quarts of fair water; then pour off the clear water, and put two

quarts of fresh water to it; strain it through a fine hair-sieve, and boil till it is as thick as a holly pudding, stirring it continually while it is boiling that it may be very smooth: Some sweeten it with sugar, and add rose or orange-flower waters; and then eat it with white or Rhenish wine, cream, or milk.

FLUOR, in *Physic*, &c. denotes a fluid; or, more properly, the flux of a body, which was before hard and solid, but is now reduced, by fusion, or fire, into a state of fluidity.

Gold and silver which remain a long time in *fluor*, kept to them by the intense heat, without losing any thing of their weight. See **GOLD**, **FIXITY**, &c.

The word *Fluor* is said to signify the habitual fluidity of any substance, or that property by which a substance cannot be rendered solid, and is employed as an epithet, to distinguish such substances from others of the same kind, but which are habitually solid, or which may be rendered solid.

Thus, acids, which are habitually fluid, as all the mineral and some vegetable acids, are called *fluor acids*, in order to distinguish them from the acid of tartar and acid essential salts, which are naturally concrete. Also volatile alkali treated with quick lime, or with metallic earths, so that it is always liquid and not crystallized, is called *fluor volatile alkali* to distinguish it from the concrete and crystallizable volatile alkali. See **ACID FLUOR**.

FLUOR is also used, by the modern mineral writers, for such soft, transparent, sparry kinds of mineral concretions, as are frequently found amongst ores and stones, in mines and quarries.

These are of a stony nature, and resemble gems; but are less hard, and are called *metals fluvi and sperti*.

FLUOR ALBI, or *Uterinus*, a kind of flux, incident to women, popularly called the *whites*.

It consists in an irregular, disorderly discharge of some corrupt humour from the uterus, near the os internum and the vagina, sometimes white and pale, like whey; sometimes yellow, green, or blackish. At first, it is usually mild, and harmless; but in time, it grows hot, sharp, and corrosive, and excoriates all the parts it touches. It is attended with a pain in the spine down a swelling of the feet and eyes, weakness, lumbago, a loss of appetite, haughtiness, and unaccountable longings, change of complexion, &c.

It generally proceeds from a relaxed habit, arising from indolence, extreme grief, or the immoderate use of coffee, tea, or other weak and watery diet; and sometimes from excessive menstrual discharges, abortions, &c.

The immediate cause of a *fluor albus*, are acidity of the fluids from which the menstrual discharge is made, or a retarded circulation of the blood through them.

In some languid habits, the *fluor albus* returns periodically, instead of the proper menstrual evacuation, till the patient's constitution is invigorated; and in many instances, it is manifest only during the absence of the menses.

It must be carefully distinguished from an ulcer in the uterus, and a gonorrhoea, which last it greatly resembles. It happens to all ages, from girls of three years old; and at all times, before, after, or even along with the menses, and even to women with child.

Those that are most subject to this disorder, are women abounding with serum, thick of lax fibres, women at the flower of their age, and girls at the approach of the menses.

Emmeller takes it for a gonorrhoea muliebis, analogous to a non-violent gonorrhoea in men, flowing out of the glandule of the prostate.

What the coriza is in the nostrils; too much weeping in the eyes; and coughing and hawking in the fauces; that, according to Emmeller, is this *fluor* in the uterus.

According to Pinnaeus, all the difference between the venereal gonorrhoea and a *fluor albus*, is, that the humour evacuated in the latter is viscid, and in the former quite thin and leucous. The same author adds, that the *fluor albus* can only be cured by medicines proper for the venereal disease.

Altreus distinguishes this disorder into the lymphatic, semilucidous, and lachryous: Dr. Shebhears says, that the *fluor albus*, the hectic fever, and the diabetes, are of the same general kind, and that they are caused by a defect of vital heat in different circumstances.

Other authors distinguish this disease into two kinds, the benign and the malignant; the first is simple, the other complicated with the venereal disease. The simple *fluor albus*, though called benign in comparison of the other, is yet very difficult to cure, and is always the more so, the longer it has continued upon the person; and very often the common methods by medicine fail, unless the cause and manner of life be changed. But though it is the most difficult of cure, it is of less danger than many other

diseases, for many women have had it many years, try a great part of their lives even to old age, and that without any great hurt. Indeed it very rarely flows to that height as to injure the strength of health, farther than a paleness of the face, and a timid look, and a looseness of the limbs: but if this discharge, when it has been many years habitual to a person, be stopped by any improper methods, it often brings on very terrible complaints. The worst effect of the *fluor albus* is that, when of long standing, it usually renders women barren; and its principal difficulty of cure is this, that it will often seem to give way to medicines, but return afterwards with all its former violence; nay when people seem ever to be perfectly cured of it, it often returns, and the whole method is to be gone through again. The *fluor albus*, while it only attends the flowing of the menstrual discharge, is a thing of no great moment; but when those discharges stop, and this matter becomes more acrid, and is voided in larger quantities, it then becomes a disease that calls for all the art of the physician to remedy it; for, in some persons, it brings on finally hectic and wasting of the flesh, and in others cichexia, oedema, and dropsies.

Method of cure. When this disease happens to a person of a plethoric habit, the first step toward a cure is bleeding in the foot to discharge part of the load of blood, lest nature should make that an occasion of converting a great part of it into serum, and throwing it upon the uterus for its discharge. After bleeding, an abstraction of the matter of the disease, and a succrative evacuation of it are to be attempted, by the more temperate uric medicines, the gentle emmenagogues and cicerans; such are amber, myrrh, and turpentine. The second of these is to be given, but in moderate doses, and the last succrals best after boiling, or when mixed with melle. The digestive salts are also to be given, and here in this case often proves a very beneficial medicine. The sperient roots, such as lavage, pimpernel, and the like, are to be given in decoction, and the leaves of beum and southernwood are no ineffectual remedies; and finally the gums are to be added, such as galsbom, ammoniacum, and tragacanth. After these altergents and preparatory medicines, gentle purges are to be given, and finally such medicines as restore the true tone of the parts; of this nature are the milder chalybeats, and decoctions of the nervous and aromatic herbs, such as celerifera, origanum, serpyllum, and the like. Junken's Conf. Med. p. 472. The diet of the patient should be solid and nourishing, but easy of digestion: her drink generous, as red port or claret, mixed with Pyrenost, Elisch, or lime-water. Singulas dissolved in milk, thyme broths, and a milk diet, have been of considerable service: tea and coffee should be avoided. The best mucilage is the Prussian bark in substance; and the cold bath is extremely useful. Dr. Cheyne recommends mild mercurials to alter, chalybeats to invigorate, and the bark and cold bathing for completing the cure.

Dr. Morgan thinks the *fluor albus* is the lymph corrupted, and assures us, that the tincture of camphire, given in a pretty strong decoction of guaiacum, has good effects when the diemper is recent, but when it is of long standing and inveterate, recourse must be had to mercurials.

FLUSH DICK. See **DECK**.

FLUSHER, in *Ornithology*, the common name of the lesser *RUTHER-BIRD*, called by authors the *lanius minor*, and the *lanius tertius* of Aldrovand. Its beak is black, long, and very strong, and a little hooked at the end: the mouth is yellow within, and the tongue jagged. It has several short bristles at the top of the beak. The middle of its back and smaller feathers of its wings are of a reddish brown; its head and rump grey: it has a broad black line on each side of the head, running from the angle of the beak; its belly is white; its throat and breast whitish, with a cast of red. Its wing-feathers are brown and black, and its legs and feet of a deep bluish black. It builds in holly-bushes and such places, and lays six or seven eggs, white at the smaller end, and ornamented with a circle and reddish spots at the other. It is common in Germany and in the northern parts of England. Ray's Ornith. p. 54.

FLUTA, in *Ichthyology*, a name given by Gaza and some authors, to the common *SEAR*, distinguished by Aristotle, by the name of the plain yellowish *SPARUS*, with a large annular black spot near the tail.

FLUYA is also a name given by Columella to the murens of Aristotle, and the ancient authors in general, as well Greek as Roman. It makes only one species of the murens, according to Aristotle; but being with him a general name, which comprehends all the sedking, the *serpens marinus* and the like, among these. This, which

was anciently called simply the *muræna*, is distinguished by that author under the name of the *muræna* having no pectoral fins, which being peculiar to this species, evidently and obviously distinguishes it at first sight from all the rest.

FLUTE, an instrument of music, the simplest of all those of the wind-kind; played, by blowing it with the mouth; and the tones or notes formed and changed by stopping or opening holes disposed for that purpose all along it. Those in common use are either the *flute à vent*, i. e. a beaked or common English *flute*, and the traverse, Helvetian, or German *flute*, the invention of which it is ascribed by Galileo and Mercurio to the Helvetians; but the antique frame of the piping fain, and a tessellated pavement of Fortuna Virilis, erected by Sylla at Rome, in which is a representation of a young man playing on a traverse pipe, with an aperture to receive his breath, shew that it is of more ancient origin.

The Latins call it *fistula*, and sometimes *tibia*, pipes from the former of which, some derive the word *flute*; though Borel will have it derived from *fistula*, a lumprey, thus called a *fistula* in *fluvio*; in regard the *flute* is long like the lumprey, and has seven holes all along it, like that fish. Hawking's Mus. p. 126.

The ancient *flutes*, or *flauts*, were made of reeds; afterwards they were of wood; and at length of metal. But how they were blown, whether as our *flutes*, or hautboys, does not appear.

Mons. Cailhien apprehends that they were founded by means of a reed; and that there were two sorts of them, in one of which the reed was visible, as in our hautboys, but concealed in the other. Beulin. Mem. 1774. vol. 9. It is plain, some had holes, which at first were but few; but afterwards were increased to a greater number; and some had none. Some were single pipes, and some a combination of several, particularly Pan's *tyrings*, which consisted of seven reeds, joined together sideways.

These seven reeds had no holes, each giving but one note, in all seven distinct notes; but at what intervals, is not known: perhaps they were the notes of the natural, or diatonic scale.

The German *flute* is different from the common ones; it is not put into the mouth, by the end, as the ordinary ones are; the end is stopped up with a plug or tampon, but the lower lip is applied to a hole a little way distant from it.

It is made equally big every where, and perforated with six holes, besides that of the mouth, and that opened by the key.

FLUTE, or **FLUTY**, is also a kind of long vessel, with flax ribs, or four-ribbers, round behind, and swelled in the middle; serving chiefly for the carrying of provisions in fleets, or squadrons of ships: though it is often used in merchandize.

The word *flute* taken for a sort of boat, or vessel, is derived according to Borel, from the ancient *flute*, a little boat. In the verbal process of the miracle of St. Catherine of Sweden, in the sixth century, we read, *Unus equum suum cum mercibus magni ponderis introduxit super contraxentem de lignis fabricatum, unguiculis distans fluta*. Upon which the Bollandists observe, that in some copies it is read *fluta*, an instrument called by the Latins *flute*; and that the word *flute*, or *fluta*, arose from *flutium*, or *clutium*, to float.

FLUTE, in weaving tapestry. See TAPESTRY.

FLUTE, or **FLUTING**, in Architecture, are perpendicular channels, or cavities, cut along the shaft of a column, or pilaster. See Vol. Archit. fig. 25, 26.

They are supposed to have been first introduced in imitation of the plaits of women's robes; and are therefore called by the Latins, *flutæ*, and *ruce*.

The French call them *canalures*, as being excavations; and we *flutes*, or *flutings*, as bearing some resemblance in the musical instrument so called.

They are chiefly affected in the Ionic order, in which they had their first rise; though they are also used in all the richer orders, as the Corinthian and Composite; but rarely in the Doric; and scarce ever in the Tuscan. Their number is usually twenty-four, though in the Doric it is only twenty.

Each *flute* is hollowed exactly in a quadrant of a circle. Between the *flutes* are little spaces that separate them, called, by Vitruvius, *fistæ*, and by us, *flits*; though in the Doric, the *flutes* are frequently made to join each other, without any intermediate space at all, the list being sharpened off to a thin edge, which forms a part of each *flute*.

In some buildings we see columns with *flutes* that go winding round the shaft, spirally; but this is rather looked on as an abuse.

Vignola determines the depth of the *flutes*, by taking the angle of an equilateral triangle for the centre. Vitruvius describes it from the middle of the square, whole side

is the breadth of the *flute*; which latter method makes them deep. The *flutes*, or *flutings*, are frequently filled up with a prominent, or swelling ornament, sometimes plain, in form of a shaft, or reed; and sometimes a little carved, or enriched, in imitation of a rope, or otherwise, and therefore called *volutes*, or *cablings*; and the columns, thus enriched, are called *rabbed columns*. This is most frequent in the Corinthian order. The *cablings*, or *flutings* up, commence from about one third of the height of the column, reckoning from the base; and are continued to the capital: that is they begin and end with the diminution of the column.

FLUTER, or **FLUTING**, are also used in Botany, to denote the stems and fruits of certain plants, which have furrows analogous to those of these columns.

FLUVIALIS, in Botany, the name given by Vaillant and Micheli to a genus of plants, called by Linnaeus *Najas*.

FLUVIATILES and **FLUVIATILIS**, fresh-water fish, a term used by naturalists to express those kinds of shell-fish which never inhabit the sea, but are found in our ponds, rivers, and ditches. These, though much less numerous than the species of sea-fish, are yet of a greater variety and beauty than is usually supposed. What are known at present, may be arranged under their proper heads in the following manner. See Sub. III. *Fluta*. N. 30.

Of the univalve kind we have two species of patella: the one having a beak at the summit of the shell, the other wanting it, and being smooth as the common patella or limpets of the sea.

Of the limax, or snails we have five species; of the fresh water snails we have three kinds; one species of the *tridacna*; three species of the *tertia*; seven species of the water *lucina*; four species of the *stellæ*, or *star shells*; four species of the *cornu ammonis*; of the bivalve fresh water shells, we have five species of the *stoma* kind; six species of the muscle kind.

Of the *patella* kind we have only one species.

Of the multivalve class, there is not one known species. The ranking of the several species to their proper genera is easy, from a remembrance of the characters of each genus of the marine shells. The limpet is a flat shell elevated into a sort of a cone at the summit. Of the snail kind, if the mouth be round, the shell is a true limax; when it is semicircular, the shell is a *tridacna*, and when it is oval or depressed, and the clavicle is long, it is then a *tridacna*. The *tridacna*, or *star-shell*, is known by its long and slender figure. The *lucina* are long shaped, and have a tail, and their mouth is narrow; and the *dolia* are of a somewhat globose figure. The *cornu ammonis*, and the umbilicated snail, are often confounded together by those who observe their external resemblance among the fresh water shells; but they are in reality sufficiently different, the *cornu ammonis* being marked on the outside with circular ridges, and divided on the inside into several separate cells, like the common fossil kind; whereas the umbilicated snail is of an even external surface, and has only one cavity within. The snail also has its mouth placed toward one side, the *cornu ammonis* in the middle: there are other differences, but these are sufficient for the distinction. The *tridacna* are known by their roundish figure; the muscles by being oblong; and the *patella* is known by its ears and its *flute*. Hist. Nat. Echir. p. 372. See SNAIL.

FLUX, **FLUXUS**, in Medicine, an extraordinary issue, or evacuation of some humour.

Fluxes are various, and variously denominated, according to their seats, or the humours thus voided; as a *flux* of the belly, uterine *flux*, hepatic *flux*, salivary *flux*, &c.

The *flux* of the belly is of four kinds, which each their respective denominations, viz. the *LIQUOR*, or *fluxus ventris*; the *COLICUS*, or *fluxus colicus*; the *DIARRHOEA*; and the *DIYENTERY*, or bloody *flux*. A wound or scarification across the crown of the head, is used in Scotland to cure *fluxus* and dysenteries. Philosoph. Trans. N. 313.

The bishop of Cloyne, in his reflections on tar-water, says, he has known a *bloody-flux* of long continuance, after divers medicines had been tried in vain, cured by TAR-WATER. But what he takes to be the most speedy and effectual remedy in a *bloody-flux*, is a cypher of an ounce of common brown root, dissolved over a fire in two ounces of oil, and added to a pint of broth, which not long since he had frequent occasion of trying, when that distemper was epidemical. Nor can he say that any to whom he advised it miscaried.

FLUX, **ABORTIVUS**, **FLUXUS ABORTIVUS**, is sometimes used among the ancients as synonymous with abortions or effusions, viz. where the embryo loses its hold and slips away. In this sense, the eagle-flux is celebrated for stopping *abortive fluxes*; for which end it was to be hung to the arm, *submersum spon uteri defendit a fluxibus abortivis*. See ABORTUS.

Among modern physicians, *alutic fluxes* are chiefly understood of a kind of hemorrhages, which sometimes precede, and bring on abortion: at other times, burst forth in the act of excretion.

In this sense, a late author defines them a species of uterine hemorrhages, happening to married women; when, after a stoppage of the menses, for three or four months successively, with a gradual swelling of the abdomen, and other signs of pregnancy, the blood begins to issue from the womb, at first sparingly, like the regular menses, but afterwards, bursts out with great force, attended with anxieties, fainting fits, and sometimes with miscarriage.

The cause is a violent separation of the secundines from the uterus, which may arise from a vehement fit of passion, or motion of the body, a fall, fright, or the like. Thunder, lightning, hot liquor, too liberal use of deobstruents, or the vessel being too hot, sometimes occasion an *alutic hemorrhage*.

FLUX of the mouth, or facial flux. See SALIVATION.

The *hepatic flux*, of the ancients, is, by several moderns, held a mere name, being, in reality, an hemorrhoidal flux, out of the hemorrhoidal veins. See HEPATIC FLUX.

Women are subject to three kinds of *fluxes* extraordinary: the first, called the *menstrua*, or *menstrual flux*, as happening every month; sometimes *even*, as keeping pace with the moon; and sometimes *irregular*.

The second is after delivery, called *LOCHIA*.

The third is irregular, and preternatural; and, for want of a better name, called *RUOR ALII*, or the *whites*.

FLUX, in *Hydrography*, a regular, periodical motion of the sea, happening twice in twenty-four hours; wherein the water is raised, and driven violently against the shores.

The *flux*, or *flow*, is one of the motions of the TIDE: the other, whereby the water subsides and retires, is called the *reflux*, or *ebb*.

There is also a kind of *refl.* or *reflux* of about half an hour, between the *flux*, and *reflux*; during which time the water is at its greatest height, called *high-water*. The *flux* is made by the motion of the water of the sea, from the equator towards the poles; which, in its progress, striking against the coasts in its way, and meeting with opposition from them, bays, and where it can find passage, as in lakes, rivers, &c. rises up, and runs into the land.

This motion follows, in time measure, the course of the moon; as it rises, or comes later every day by about three quarters of an hour; or more precisely, by forty-eight minutes; and by so much is the motion of the moon slower than that of the sun. It is always highest and greatest in full moons, particularly those of the equinoxes. In some parts, as at Mount St. Michael, it rises eighty or ninety feet, though in the open sea it never rises above a foot or two; and in some places, as about the *Mores*, there is no *flux* at all. It runs up some rivers above a hundred and twenty miles. Up the river Thames it only goes eighty, viz. near to Kingston in Surrey.

Above London-bridge, the water flows four hours, and ebbs eight; and below the bridge, flows five hours, and ebbs seven.

FLUXES, in *Metallurgy*, are certain saline matters, which cause a body otherwise not at all, or hardly fusible by fire, to melt. Fixed alkalis, nitre, borax, tartar, and common salt, are the saline matters of which *fluxes* are generally composed.

The most powerful of these, are glass of lead, and the alkaline neutral salts. These are principally used by assayers, when they would work minerals in a small quantity; but when large quantities of minerals are to be wrought on, it is seldom possible to use *fluxes* of this kind to any advantage, because of their price. In these cases, instead of these expensive *fluxes*, they use such stones as are vitrified by a gentle fire, or the fumes of the same stones when melted, which always serve their purposes much better; for the former these stones have been exposed to the fire, the more easily are they put in fusion: the reason of which seems to be, that the alkaline salt proceeding from the fuel of the fire, adheres to the fumes, and these added in large quantities to the rest of the metals in great operations, cause the said ores to melt, which are otherwise made refractory by the calcareous and inflammable stones and earths mixed with them.

The melting of gold and silver, and of their calces, is greatly promoted by glass of lead, alkaline salts, &c. but when gold and silver in the fusion itself, are to be purged from other metals and ferments, it is proper to use nitre only; or if not so, nitre must be always mixed with the other salts; for the ferments and the four less perfect metals are destroyed by nitre.

In this operation, nitre by its detonation with their sul-

phurs is in part alkalisied, and by the help of a gentle fire, turns their calces into vitreous and much attenuated scoriae.

From hence, the reason is plain why gold and silver, when made brittle, are readily restored to their malleability by nitre: for the ferments, and among the metals, lead, and tin, most of all communicate this fault to gold and silver; but these being changed, as before observed, by nitre, are then rejected by gold and silver in a simple fusion, so that they can no longer mix with these metals, unless they are themselves first again reduced to their metallic state; and there is besides this, no other body that can be mixed with silver and gold to render them brittle, unless crude charcoal happening to fall into the vessel, wherein these metals are melted, should impregnate them with something artificial, there being some arsenic contained in each of this kind; as has been demonstrated by Stahl and Hoffman.

The less perfect metals, and the ferments melt more easily by adding salts to them, than of themselves: they always, however, lose a great deal of their substance by this means; and this is more particularly the case, in regard to copper and iron. To mend this, it is necessary to add some kind of fat body, which prevents the destruction, and even reduces the metals already destroyed; and this is the more necessary, when the calces prepared either by burning, or by a detonation with nitre, are to be reduced.

The most proper *flux* on these occasions, is that usually known among metallurgists under the name of the *black flux powder*, and is thus prepared.

Take of common nitre, one part, of crude tartar thoroughly dried, two or three parts: make them separately into very fine powder, then grind them well together, and afterwards put them into an earthen pan, narrow at the orifice, not glazed within, and of capacity three times larger than the powder will take up: put this into a gentle fire, and as soon as the mass begins to flame with some noise, that the orifice of the vessel with a flux after the detonation is over, you will find in the vessel a black oily alkaline salt, which is very easily fusible in the fire, and is called the *black flux*. keep it in a dry warm place, and in a vessel closely shut, to prevent its growing moist.

Tartar being burnt either alone in vessels closely shut, or detonated with nitre, is very readily alkalisied; and thus retains a considerable quantity of the oil which it contains in great abundance, and which is fixed enough to remain with it, after this operation; and for this reason it very easily becomes a reducing *flux*, which, on account of its alkaline salts, dissolves earths and stones, and changes them into an imperfect kind of glass by a moderate melting fire; but the oil being of a more fixed nature, still remains concentered therein, and is of great use both to preserve metals from being destroyed, and to reduce such as have been destroyed already.

If the pot in which this *flux powder* is made be glazed within, and part of the glazing comes off, and mixes with the *flux*, and melts with it, it is again reduced to lead, and may thus disappoint the artifice; for this crust of glazing is given to earthen vessels by lead or lime-ge. Another caution is also necessary; which is, that *fluxes* must be kept and used very dry; for moist salts from very much; and when the operations are made in close vessels, if the fire is quickly increased, not being able to get rid of the moisture, the vessels will split and break.

Besides the black, assayers are also very fond of a white *flux powder*, which is prepared only of equal parts of nitre and tartar detonated in the same manner. For in this case the oil of the tartar is almost entirely consumed by the abundance of the nitre, and the remaining mass becomes a whitish or ash-coloured salt, which is also more powerfully alkaline, and thus than the foregoing. This *flux* is very efficacious in the dissolving of stones, and earths; but for want of its being of a less relative virtue, and destroys the metal, when the fire is continued a little longer than is required.

By crude *flux*, is meant the mixture of nitre and tartar in any proportions, without detonation.

Flux powders are of great service also to reduce metals out of their respective calces, and to free them from the stones in which they are embodied; but when the refractory calx of iron is to be reduced by a great and long lasting fire, these *fluxes* being greatly attenuated, though confined in close vessels, part from their oily principle, and their alkaline salt remaining, begin to corrode and consume the vessels, or what matter forever they are made, and finally make their way through them and get out. The hurt of these accidents is prevented by adding coal dust, which will never part with its oil, without the help of a free air; and the others by an admixture of common glass, made of a due mixture of flint and fixed alkali.

lali. For this is sufficiently fusible, and readily melts with the *flux*, and by its viscosity, in some sort coagulates, and holds the salt of the *flux* together, and prevents it from too easily corroding the vessels. *Cramer, Art. Al. p. 48. 52.*

The great secret in making and improving *fluxes* for the ores of metals, is not only to find such ingredients as will be of efficacy to separate the metal already ripened in the ore, but even to mature and ripen the yet immature part of it in the fire; and something of this kind we apprehend might be effected, as there is great reason to believe, that certain *fluxes* will obtain a much larger yield of metals from certain ores than other *fluxes* in common use, though esteemed of the best, and perhaps of the dearest kind; thus clean iron filings will often do more than borax, but as the scales and rust of iron have commonly been used under the name of iron in *fluxes*, few operators know the value of pure iron in that intention, and many advantages are now obtained by mixing one with another of the same denomination, and with the scales or remnants of metals in the way of a *flux*.

The *fluxes* for the ores of metals form in general reducible to two kinds, the vitreous and the saline. The vitreous are those which commonly have a glassy form, or readily assume one in the fire; the principal of these are glass of lead, glass of antimony, and borax.

By the saline *fluxes*, authors generally mean those which are composed of salts, whether tartar, nitre, fixed alkali, or the like, as the black *flux*, fuming, pot-still, and the like. The vitreous *fluxes* form dissolved more immediately to act upon the fusing or vitreous matter, where with the flubborn ores are frequently mixed, and the saline kind to act more immediately upon the matter of the ore itself, for the due exclusion or separation of the metal.

The more kindly ores require no *fluxes* at all, and often they contain in themselves the necessary matter for the *flux*; thus there are copper ores, which being only ground to powder, and put into a common wind furnace, will yield as much pure metal at the full operation, as can be produced from them, by all the *fluxes*. *Shaw's Lectures, p. 256.*

Powder of antimony is a very good *flux* powder. By this alone may you readily melt iron or steel in a crucible, with an ordinary charcoal fire.

Some of the cheapest and most powerful *fluxes* now in use are, dried wine-les, dried cow-sun, and horse-dung, dried river-mud, fuller's-earth, iron filings, common salt, potash, and sand. These may be used in the larger works, as nitre, tartar, borax, sal ammoniac, and mercury sublimate, in the less, as iron compound *fluxes*, they are very numerous, almost every operator having his particular nostrum; and it is plain that some *fluxes* are better adapted to the ores of lead metals than others; but certainly a few general ones might be fixed upon, one or other of which would answer all the operator's expectations.

The three following preparations are all very general, very powerful, and not expensive. 1. Take of nitre, prepared by long boiling in lime-water, of sea-salt melted in the fire, of sand, and of dry wine-les, each one part; glass of lead, three parts, and powdered glass, eight parts; mix them all well together, and use them in an equal weight with flubborn ore. 2. For a still stronger *flux*, take equal parts of white tartar, common salt, and nitre prepared as above; calcine all together to a white powder, and mix with it its own weight of glass of lead; of this *flux* add two parts to one part of the most flubborn ore. 3. For a very powerful saline *flux*, take of the strongest soap-balls's less four pounds, of white tartar and common salt, melted in the fire, each one pound; boil these together, with four gallons of human urine, to a dry salt. This *flux* is particularly serviceable where sulphur and cobalt abound, and render the ore very refractory. *Shaw's Lectures, p. 257.*

Fluxes, in Enamelling, are used for forming the grounds and colours: there are two kinds of substances which enter the composition of enamel *fluxes*, viz. the vitreous matters, which consist of salts, lead and arsenic, and the correctives of these, which are calcined flints, sand, or such calcareous matter, which give body and firmness to the fusing composition, without discolouring or changing the proper fusing qualities, unless by diminishing in a degree their vitriolative power. The most active *flux* among salts is borax, the next is lead, arsenic, joined with some other body already vitrified and hereby fixed, is the next powerful *flux*; and the several kinds of salts succeed, of which sea salt possesses the greatest fusing power. Though these are not strong enough by themselves, yet, as they are colourless, they are necessary to be compounded with lead, or substituted for it, with the aid of borax, for purposes, in which the *flux* must be wholly destitute of colour. *Fluxes* of all

kinds are prepared by levigating the ingredients of which they consist on a porphyry floor, with a muller of the same matter or of flint; or in a mortar of agate or flint, with an agate pestle; or for the sake of expedition, a mortar and pestle of the common green glass may be previously used. This levigated matter must be then put into melting pans, and placed in a furnace, where the heat is nearly that of a strong culinary fire; and when the vitrification is perfect, which may be known by the matter's being transparent and free from bubbles, it must be poured out on an iron plate from a ruit, and when cold powdered and kept for use. See *Enamelling*.

Fluxes, in the Manufacture of Glass, are soft lead, pen-still, nitre, sea-salt, borax, arsenic, the ferris of forges, commonly called tinkers, and wood-ashes. See *Glass*.

FLUXION, in Medicine, a sudden collection of morbid matter in any part of the body.

Fluxion will either from the weakness, facility, and insensibility of the part affected, which does not sufficiently protrude, or expel, the humours naturally received into it, or from the derivation of some extraordinary quantity of succulent matter from some other part.

This latter is properly called *hemorrhoea*, and, by the ancients, *strophala*.

A *fluxion*, or *effluxion*, on the trachea and lungs, is called a *cataxsis*.

Fluxion, in the *Newtonian Philosophy*, denotes the velocity with which a flowing quantity is increased by its generative motion: by which it stands contradiistinguished from *flux* or the flowing quantity, which is gradually, and indefinitely increasing, after the manner of a space which a body in motion describes.

Or, a *fluxion* may be more accurately defined, as the magnitude by which any flowing quantity would be uniformly increased in a given portion of time, with the generating velocity at any preposed position, or instant, supposing it from thence to continue unvariable.

Thus, if the point *m* move from *A*, and generate the right line *A m*, *Tab. II. Geometry, fig. 26.* and the velocity at *B* be such as would be sufficient, supposing it to continue uniform from that point, to describe the line *B r* in the given time; then *B r* represents the *fluxion* of the variable line *A m* in that position. The rectangle *A S*, *fig. 30.* may be conceived to be generated by the parallel motion of the invisible line *m s* between *A F* and *B G*; and since *B r* is the *fluxion* of *A m*, the rectangle *B r* *h s* will be the space which would be uniformly described by *m s*, whilst *A m* would be uniformly increased by *m s*, and it is, therefore, the *fluxion* of the generated rectangle *A B S r*. Further, if the curvilinear space *A m s*, *fig. 31.* be generated by the parallel motion of *m s*, considered as variable, and *B r* be the *fluxion* of *A m*, the rectangle *B r* *h s* would be uniformly generated with the velocity, with which a body *s* is generated, and with which the space *A m s* is increased in the position *B*; when the length and velocity of *m s* are supposed to continue unvariable from that position, and, therefore, agreeably to the definition, will be the *fluxion* of the generated space *A m s*.

From this definition it appears, that the *fluxions* of quantities are, always, as the velocities by which the quantities themselves increase in magnitude.

Mr. Simpson observes, that there is an advantage in considering *fluxions*, not as mere velocities, but as magnitudes which their velocities would, uniformly, generate in a given time: the imagination is not here confined to a single point, and the higher orders of *fluxions* are rendered much more easy and intelligible. And though Sir Isaac Newton defines *fluxions* to be the velocities of motions, yet he hath recourse to the increments or moments, generated in equal particles of time, in order to determine those velocities, which he afterwards teaches us to express by finite magnitudes of other kinds. *Simpson's Fluxions, vol. I. part. p. 6. and p. 2. &c.*

Fluxions, method of, is the arithmetic and analysis of *fluxions*, or flowing quantities.

Foreigners usually denote the method of *fluxions*, the arithmetic, or analysis, of infinitely, or rather indefinitely, small variable quantities; or the method of finding an infinitesimal, or infinitely small quantity, which, being taken an infinite number of times, becomes equal to a given quantity.

Sir I. Newton, and, after him, the English authors, call these infinitely small quantities, *moments*; considering them as the momentary increments, or decrements, of variable quantities, e. g. of a line considered as generated by the flux of a point, or of a surface generated by the flux of a line.

Accordingly, the variable quantities are called *fluxes*, or flowing quantities; and the method of finding either the *fluxion*, or the *flux*, the method of *fluxions*.

Mr. Leibnitz considers the same infinitely small quantities

as the differences, or differentials, of two quantities; and calls the method of finding these differences, the *differential calculus*. Each of these ways of considering and denominating, has its advantages, which the retainers to this or that method strenuously assert.

Flowing quantities, i. e. such as, in the genesis of figures by local motion, are continually increasing and diminishing, are certainly very properly denominated *fluents*; and as all figures may be conceived as to be generated, the infinitely small increments or decrements of such quantities, are very naturally denominated *fluxions*.

Beside this difference in the name, there is another in the notation.

Sir I. Newton expresses the *fluente* of a quantity, as x , by a dot placed over it, as $\dot{x}$; and M. Leibnitz expresses his differential of the same x , by prefixing a d , as dx ; each of which methods of notation has likewise its advantage.

Setting aside these circumstances, the two methods are the same.

The method of *fluxions* is one of the greatest, most subtle, and sublime discoveries of this, or, perhaps, of any age; it opens a new world to us, and extends our knowledge, as it were, to infinity; it carries us beyond the bounds that seemed to have been prescribed to the human mind, at least infinitely beyond those to which the ancient geometry was confined.

The history of this important discovery, as fresh as it is, is a little dark, and imbricated. Two of the greatest men of this age do both of them claim the invention, Sir I. Newton, and M. Leibnitz; and nothing can be more glorious for the method itself, than the zeal wherewith the partisans of either side have asserted their title.

To give the reader a just view of this noble dispute, and of the pretensions of each party, we shall lay before him the origin of the discovery, and mark where each claim commenced and how it was supported.

The first time the method made its appearance in public, was in 1684, when M. Leibnitz gave the rules thereof in the *Leipzic Acta* of that year; but the demonstrations he kept to himself. The two brothers, the Bernoullis, were presently struck with it, and found out the demonstrations, though very difficult; and practised the calculus with surprising success.

However, M. Leibnitz began to propose his differential method in a letter, dated the 21 Jan. 1677, in which he exactly pursues Dr. Barrow's method of tangents, published in 1670; and Sir I. Newton communicated his method of drawing tangents to Mr. Collins, in a letter dated 10 Dec. 1672; which letter, together with another dated 13 June, 1676, were sent to M. Leibnitz by Mr. Oldenburgh, in 1676. So that there is a strong presumption that he might avail himself of the information contained in these letters, and other papers transmitted with them, and also in 1675, before the publication of his own letter, containing the first hint of his differential method. And it sufficiently appears, that Sir I. Newton had invented his method before the year 1666, and that he actually made use of it in his *Compendium of Analysis and Quadrature of Curves* before that time. His attention seems to have been directed this way, even before the plague which happened in London in 1665 and 1666, when he was about twenty-three years of age; and, therefore, there is no foundation for the hint suggested by the authors of the *Encyclopédie Art. Différentielle*, that Sir Isaac borrowed the differential method from Dr. Barrow.

This is all we hear of it, till the year 1687, when Sir Isaac Newton's admirable *Principia* came forth, which is almost wholly founded on the same calculus.

The common opinion, at that time, was, that Sir Isaac, and M. Leibnitz, had each invented it about the same time; and what confirmed it was, that neither of them made any mention of the other; and that, though they agreed in the substance of the thing, yet they differed in their ways of conceiving it, called it by different names, and used different characters.

In effect, M. Leibnitz's character was supposed, by foreigners, to be somewhat more commodious than that of Sir Isaac Newton; accordingly, the method from spreading itself throughout Europe, M. Leibnitz's character went with it; by which means the geometers were infensibly accustomed to look on him as the sole, or principal inventor.

The two great authors themselves, without any seeming concern, or dispute, as to the property of the invention, enjoyed the glorious prospect of the progress continually making under their auspices, till the year 1699, when the peace began to be disturbed.

M. Fatio, in a treatise *Of the Line of swiftest Descent*, declared, that he was obliged to own Sir Isaac Newton as the first inventor of the differential calculus, and the

first by many years; and that he left the world to judge, whether M. Leibnitz, the second inventor, had taken any thing from him. This precise distinction between first and second inventor, with the suspicion it incited, raised a controversy between M. Leibnitz, supported by the editors of the *Leipzic Acta*; and the *Leipzic geometers*, who declared for Sir I. Newton. Sir Isaac himself never appeared on the scene; his glory was become that of the nation; and his adherents, warm in the cause of their country, needed not him to animate them.

Writings succeeded each other but slowly, on either side; probably, on account of the distance of places; but the controversy grew till hotter and hotter; till, at length, it came to such pass, that, in the year 1711, M. Leibnitz complained to the Royal Society, that Dr. Keill had accused him of publishing the method of *fluxions* invented by Sir I. Newton, under other names, and characters.

He insisted, that nobody knew better than Sir Isaac himself, that he had stolen nothing from him; and required, that Dr. Keill should publicly disavow the ill construction which might be put on his words.

The society, here appealed to as a judge, appointed a committee to examine all the old letters, papers, &c. that had passed among the several mathematicians, relating to the points; and, after a strict examen of all the evidences that could be procured, gave in their report to this purpose: "That Mr. Leibnitz was in London in 1673, and kept a correspondence with Mr. Collins by means of M. Oldenburgh, till Sep. 1676, when he returned from Paris to Hanover, by way of London and Amsterdam; that it did not appear that M. Leibnitz knew any thing of the differential calculus before his letter of the 21st June, 1677, which was a year after a copy of a letter wrote by Sir I. Newton, in the year 1672, had been sent to Paris to be communicated to him, and above four years after Mr. Collins began to communicate that letter to his correspondents; wherein the method of *fluxions* was sufficiently explained; to let a man of his sagacity into the whole matter; and that Sir I. Newton had even invented his method before the year 1666, and, of consequence, fifteen years before M. Leibnitz had given any thing on the subject in the *Leipzic Acta*." And thence they concluded, that Dr. Keill had not at all injured M. Leibnitz in what he had said.

The society printed this sentence of theirs, together with all the papers and materials relating thereto, under the title of *Commercium Epistolicum de Analysi Promota*, Lond. 1712. This book was carefully distributed through Europe, to vindicate the title of the English nation to the discovery; for Sir Isaac, as already hinted, never appeared in it; whether it were that he trailed his honour with his compatriots, who were zealous enough in the cause; or whether it were that he was even superior to the glory thereof.

M. Leibnitz and his friends, however, could not show the same indifference; he was accused of a theft, and the whole *Commercium Epistolicum* either expresses it in terms, or insinuates it. Soon after the publication thereof, a loose sheet was printed, at Paris, in behalf of M. Leibnitz, then at Vienna. It is wrote with great zeal and spirit; and maintains, boldly, that the method of *fluxions* had not preceded that of *differences*; and even insinuates, that it might have arisen from it. The detail of the proofs, on each side, would be too long, and could not be understood without a large comment, which must enter into the deepest geometry.

M. Leibnitz had begun to work upon a *Commercium Epistolicum*, in opposition to that of the Royal Society; but he died before it was completed.

A second edition of the *Commercium Epistolicum* was printed at London in 1722; where Sir Isaac Newton, in the preface, account, and annotations, which were added to that edition, particularly answered all the objections which M. Leibnitz and M. Bernoulli were able to make since the *Commercium* first appeared in 1712. See also Raphson's Hist. *Fluxionum*. From the last edition of the *Commercium*, and the various original papers contained in it, it evidently appears that Sir Isaac Newton had discovered his method of *fluxions* many years before M. Leibnitz's pretensions.

It must be owned, that there are strong presumptions in favour of M. Leibnitz's presumption; we mean, that he was no plagiarist: for that Sir Isaac Newton was the first inventor, is past all dispute; his glory is secure; the reasonable part, even among the foreigners, allow it; and the question is only, whether M. Leibnitz took it from him, or fell upon the same thing which he, for, in his *Theory of Abstract Notions*, which he dedicated to the Royal Academy, in 1671, before he had seen any thing of Sir I. Newton's, he already supposed infinitely small quantities,

which is no parallelogram, may be considered, in the strictest geometry, as if it really were one, because it is infinitely small; and the error, of consequence, infinitely little, i. e. none.

So that, to measure it, there needs nothing but to multiply an ordinate of the parabola by the infinitely small portion of the axis corresponding thereto. Thus we have the element of the whole parabola; which element being tallied, by the inverse method, to a finite magnitude, is the whole surface of the parabola.

This advantage, so peculiar to the geometry of infinites, of being able, without any error, to treat little arches of curves as if they were right lines; curvilinear spaces, as if rectilinear ones, &c. enables it not only to go with more ease and readiness than the ancient geometry, to the same truths, but to reach a great number of truths which were inaccessible in the other.

Its operations, in effect, are more easy, and its discoveries more extensive, and simplicity and universality are its distinguishing characters.

The preceding observations are more properly applicable to the method of infinites and indivisibles than to the Newtonian method of fluxions, in which magnitudes of various kinds are capable of increase, not by a repeated accession of parts, but by a continued motion of flux. See the sequel of this article.

PROPOSITION given, to find the fluxion quantity belonging to any. To have the doctrine of the inverse method complete, and keep pace with that of the direct, we will apply it in the same cases.

1. In general, to express the variable quantity of a fluxion, there needs nothing but to write the letters without the dots, or to substitute the variable or flowing letter for its fluxion. Thus the flowing quantities of x, y, z , are $\dot{x}, \dot{y}, \dot{z}$.

2. To find the fluxion of a compound fluxional expression consisting of the products of two or more flowing quantities drawn into their fluxions; or which consist of the fluxion of each quantity drawn into the other, or product of the rest of the quantities.

Multiply the flowing quantities together; and the product is the fluxion required. E. gr. the fluxion of $xy + xz$ is $\dot{x}y + x\dot{y} + \dot{x}z + x\dot{z}$; $\dot{x}y + \dot{x}z$, &c.

3. To find the fluxion of a fraction. The following rule will serve in many cases. Divide the last term in the numerator by the fluxion of the negative square root of the denominator; then divide this quotient by the affirmative square root of the denominator for the required fluxion.

Thus, the fluxion of $\frac{xy - yz}{y}$ is $\frac{\dot{x}y - y\dot{z}}{y}$.

4. To find the fluxion of an expression compounded of different fluxional terms connected together by the signs $+$ and $-$.

Find the separate fluxions of the different terms, and connect them together by the signs of their respective fluxions. Thus, the fluxion of $ax + xy + xz - \frac{y}{x}$

$$\text{is } a\dot{x} + x\dot{y} + \dot{x}z - \frac{\dot{y}}{x}.$$

5. To find the flowing quantity belonging to the fluxion of any power, either perfect, or imperfect. Take the fluxional letter, or letters, out of the equation; then augment the index of the fluxion by 1, or unity; lastly, divide the fluxion by the index of its power to increased by unity.

Thus suppose $3x^2\dot{x}$ proposed; by taking away $\dot{x}$ it will be $3x^2$; and by increasing its index by unity, it will be $3 \times 3x^2$; then dividing it by 3, its now (augmented) index, the quotient will be $x^2\dot{x}$, the flowing quantity required.

Again, the fluxion of $\frac{x^{n-m}}{x^m}$ will be $\frac{x^{n-m}\dot{x}}{x^m}$. In compound fluxional expressions, if the fluxional part is equal, or in an invariable ratio to the fluxion of the quantity under the vinculum, the fluxion may be had by adding 1 to the index of the power, and dividing by the fluxion of the quantity under the vinculum drawn into the index of the power thus increased. E. gr. the fluxion

$$\text{of } \frac{x + x^2}{x^2} \times 3x + 0 \cdot x \dot{x} \text{ is } \frac{x + x^2}{3x + 0 \cdot x} \times \dot{x} = \frac{x + x^2}{3x}$$

$$\text{the fluxion of } \frac{x + x^2}{3x} \times \dot{x} = \frac{x + x^2}{3} \times \dot{x} = \frac{x\dot{x} + x^2\dot{x}}{3}, \text{ and the fluxion}$$

$$\text{of } \frac{x + x^2}{3} \times \dot{x} = \frac{x\dot{x} + x^2\dot{x}}{3} = \frac{x\dot{x} + x^2\dot{x}}{3}$$

By these methods the fluxion is found when the fluxion is given; and the rules are derived from those of the direct method; as the rules in division and evolution in algebra are deduced from those of multiplication and involution. As when a fluxion consists of a variable and invariable

part, the latter does not appear in the fluxion; so when any fluxion is proposed, it is only the variable part of the fluxion that can be derived from it. If x represent any fluxion that may be proposed, the variable part of the fluxion will be equal to $\dot{x}$; for supposing y to be any variable quantity, if $x + y$ could represent the fluxion of x , then $x + y$ would be equal to $\dot{x}$, and $y = \dot{x} - x$, or y would be invariable, against the supposition. But supposing K to represent any invariable quantity, then $x + K$ may generally represent the fluxion of x . If it be required to find such a fluxion of x as shall vanish when x is supposed to vanish, it can be no other than $\dot{x}$; and if it be required that the fluxion should vanish when x is equal to any given quantity a , then by supposing $x + K$ to vanish when x becomes equal to a , we shall have $a + K = 0$, or $K = -a$; whence the fluxion is $\dot{x} - a$. In the same manner, the fluxion of $-x$ may be generally represented by $K - x$. When a fluxion that is proposed coincides with any of those which were deduced from their fluxions in the preceding articles, the variable part of the fluxion required must coincide with that which was there proposed. As division in algebra leads us to fractions, and evolutions to surds; so the inverse method of fluxions leads us often to quantities that are not known in common algebra, and that cannot be expressed by common algebraic symbols. MacLaurin's Flux. art. 7 & 15.

We cannot here pretend to enter into a detail of the rules of the inverse method of fluxions. We shall only observe in general, that a fluxion being proposed, its fluxion may sometimes be found accurately in algebraic terms; but this is far from being always possible; and recursive must sometimes be had to a converging series. Thus, if $x^a - x$ were proposed, the variable part of the fluxion is found by adding unity to the exponent of the power, dividing by the exponent thus increased, and by the fluxion of the root; that is, the invariable part of the fluxion of $x^a - x$ will be $\frac{a-1}{a} x^{a-1} \dot{x}$. But in many cases

this fluxion requires the addition or subtraction of some constant quantity to render it complete, which can only be known from the nature of the problem under consideration; e. gr. the fluxion of $x^a - x$ may be either represented by $\frac{a-1}{a} x^{a-1} \dot{x}$, or by $\frac{a-1}{a} x^{a-1} \dot{x} + c$, because c being constant, the fluxion of $x^a - x + c$, as well as of $x^a - x$, is $\frac{a-1}{a} x^{a-1} \dot{x}$. To find this invariable quantity that must be added or subtracted, is to correct the fluxion. In order to do this, the best way is to consider how much the variable part of the fluxion, first found, differs from the truth, in that particular circumstance when the required quantity which the whole fluxion ought to express is equal to nothing; then, that difference added to or subtracted from the variable part, as occasion requires, will give the fluxion truly corrected. For, since the difference of two quantities flowing with the same celerity, or having equal fluxions, is either nothing at all, or constantly the same, the difference in that circumstance will likewise be the difference in all other circumstances; and, therefore, being added to the lesser quantity, or subtracted from the greater, both become equal. Let the variable quantities x and y be first supposed to begin their existence together or to be generated at the same time: e. gr. 1. Let $y =$

$$a^2 x^2, \text{ the fluxion will be } y = \frac{a^2 x^2}{2} \dot{x}, \text{ if } y = a^2 x^2 \text{ vanish;} \\ \text{er, because } x \text{ is also } \dot{x}, \text{ and the fluxion needs no correction. 2. Let } y = \frac{a^2 + x^2}{4} \times \dot{x}, \text{ and } y \text{ will be } =$$

$$\frac{a^2 + x^2}{4} \dot{x}; \text{ but when } y = a^2 \text{ and } x = a, \frac{a^2 + a^2}{4} \text{ becomes } =$$

$$\frac{a^2}{2}; \text{ and, therefore, } \frac{a^2 + x^2}{4} \text{ always exceeds } y \text{ by } \frac{a^2}{4}, \text{ and}$$

$$\text{the fluxion properly corrected will be } y = \frac{a^2 + x^2}{4} \dot{x} =$$

$$a^2 x + \frac{3a^2 x^3}{2} + a x^3 + \frac{a^3}{4}. \text{ But this fluxion may be found without correction, by expanding } \frac{a^2 + x^2}{4} \text{ in the original equation, which will become } y = \frac{a^2}{4} + \frac{3a^2 x^2}{4} + \frac{a^2 x^4}{4} + \frac{a^2 x^6}{4}, \text{ whence } y = \frac{a^2}{4} + \frac{3a^2 x^2}{4} + \frac{a^2 x^4}{4} + \frac{a^2 x^6}{4}.$$

$$3. \text{ Let } y = \frac{a^2 - x^2}{3} \dot{x} \times x; \text{ then } y = \frac{a^2 - x^2}{3} \dot{x}, \text{ and}$$

$$y \text{ being } = \frac{a^2 - x^2}{3} \dot{x} \text{ becomes } = -\frac{a^2}{3}, \text{ therefore } -$$

$$\frac{a^2 - x^2}{3} \text{ is too little by } \frac{a^2}{3}; \text{ and the fluxion corrected will be } y = \frac{a^2 - x^2}{3} \dot{x}, \text{ &c.}$$

In the solution of other problems, the value of y will be equal

Fluxions, and of its inventor, Sir Isaac Newton. An answer to the Analyst, under the title of Geometry no Friend to Infidelity, appeared very early under the name of Philaëthes Cantabrigiæ, supposed to be Dr. Jurin; a second, by the same hand, in defence of the first, intitled, The Minute Mathematician, or the Free-thinker no just Thinker, published in 1735; a Discourse of *Fluxions*, by Mr. Robins, first published in 1735 (see his Collection of Tracts, by Wilton, vol. ii.); a Treatise of Sir Isaac Newton's, with a Commentary by Mr. Colson; and several other pieces were published on this subject; particularly a very full and excellent treatise of *Fluxions*, by Mr. MacLaurin, late professor of mathematics in the University of Edinburgh, containing not only a most distinct account of the principles of *Fluxions*, but also of the chief discoveries in geometry, and mathematical philosophy of this age. The curious may find an elegant account of this treatise in the Philosophical Transactions, No 468, 469.

We presume that Mr. MacLaurin's demonstrations are sufficient to satisfy the most scrupulous; it would exceed the bounds of our design to intertext at length here; but we cannot omit mentioning what seems necessary to explain and illustrate the notion of *Fluxions*; and the principles on which this method of computation is founded. In the doctrine of *Fluxions*, magnitudes we conceive to be generated by motion; and the velocity of the generating motion is the *Fluxion* of the magnitude. Lines are supposed to be generated by the motion of points; the velocity of the point that describes the line, is its *Fluxion*, and measures the rate of its increase or decrease. When the motion of a point is uniform, its velocity is constant, and is measured by the space described by it in a given time; when the motion varies, the velocity at any term of the time is measured by the space which would be described in a given time, if the motion was to be continued uniformly, from that term, without any variation. And this is analogous to the general doctrine of powers, or may be considered as a particular application of it. As a power which acts continually and uniformly is measured by the effect that is produced by it in a given time, so the velocity of an uniform motion is measured by the space that is described in a given time. If the action of the power vary, then its exertion at any rate of the time is not measured by the effect that is produced after that term in a given time, but by the effect that would have been produced if its action had continued uniform from that term; and in the same manner, the velocity of a variable motion at any given term of time is not to be measured by the space that is actually described after that term in a given time, but by the space that would have been described, if the motion had continued uniformly from that term. If the action of a variable power, or the velocity of a variable motion, may not be measured in this manner, they must not be susceptible of any mensuration at all. When it is supposed that a body has some velocity or other at any term of the time, during which it moves, it is not therefore supposed, that there can be any motion in a term, limit or moment of time, or in an indivisible point of space; and as velocity is always measured by the space that would be described by it, continued uniformly for some given finite time, it cannot surely be said, that geometers pretend to conceive motion or velocity without regard to space or time, as the author of the Analyst often suggests. This is a short view of the nature and tendency of the doctrine of *Fluxions*, which we shall now proceed to explain more particularly.

We have already said that lines may be conceived as generated by the motion of points; in like manner surfaces may be conceived as generated by the motion of lines; solids by the motion of surfaces; angles by the rotation of their sides; the flux of time being supposed to be always uniform. The velocity with which a line flows, is the same as that of the point which is supposed to describe or generate it. The velocity with which a surface flows, is the same as the velocity of a given right line; that, by moving parallel to itself, is supposed to generate a rectangle which is always equal to the surface. The velocity with which a solid flows, is the same as the velocity of a given plain surface, that, by moving parallel to itself, is supposed to generate an erect prism or cylinder that is always equal to the solid. The velocity with which an angle flows, is measured by the velocity of a point, that is supposed to describe the arch of a given circle, which always subtends the angle, and measures it. In general, all quantities of the same kind (when we consider their magnitude only, and abstract from their position, figure, and other affections) may be represented by right lines, that are supposed to be always in the same proportion to each other as these quantities. They are represented by right lines in this manner in Euclid's Ele-

ments, in the general doctrine of proportion, and by right lines and figures in the data of that accurate geometer. In this method likewise, quantities of the same kind may be represented by right lines, and the velocities of the motions by which they are supposed to be generated, by the velocities of points moving in right lines. All the velocities we have mentioned are measured, at any term of the time of the motion, by the spaces which would be described in a given time by these points, lines, or surfaces, with their motions continued uniformly from that term.

A *Fluxion* being the velocity with which a quantity flows, at any term of the time whole it is supposed to be generated, is therefore always measured by the increment or decrement that would be generated in a given time by this motion, if it was continued uniformly from that term without any acceleration or retardation; or it may be measured by the quantity that is generated in a given time by an uniform motion, which is equal to the generating motion at that term.

Time is represented by a right line that flows uniformly, or is described by an uniform motion; and a moment, or termination of time, is represented by a point or termination of that line. A given velocity is represented by a given line, the same which would be described by it in a given time. A velocity that is accelerated or retarded, is represented by a line that increases or decreases in the same proportion. The time of any motion being represented by the base of a figure, and any part of the time by the corresponding part of the base, if the ordinate at any point of the base be equal to the space that would be described, in a given time, by the velocity at the corresponding term of the time continued uniformly, then any velocity will be represented by the corresponding ordinate. The *Fluxions* of quantities are represented by the increments or decrements, described in the foregoing paragraph, which measure them; and instead of the proportion of the *Fluxions* themselves, we may always substitute the proportion of their measures.

When a motion is uniform, the spaces that are described by it in any equal times are always equal. When a motion is perpetually accelerated, the spaces described by it in any equal times that succeed after one another, perpetually increase. When a motion is perpetually retarded, the spaces that are described by it in any equal times that succeed after one another, perpetually decrease.

It is manifest, conversely, that if the spaces described in any equal times are always equal, then the motion is uniform. If the spaces described in any equal times that succeed after one another perpetually increase, the motion is perpetually accelerated; for it is plain, that if the motion was uniform for any time, the spaces described in any equal parts of this time, would be equal; and if it was retarded for any time, the spaces described in equal parts of this time that succeed after one another would decrease; both of which are against the supposition. In like manner it is evident, that a motion is perpetually retarded, when the spaces that are described in any equal times that succeed after one another, perpetually decrease. The following axioms are as evident, as that a greater or lesser space is described in a given time, according as the velocity of the motion is greater or less.

Axiom 1. The space described by an accelerated motion is greater than the space which would have been described in the same time, if the motion had not been accelerated, but had continued uniform from the beginning of the time.

Axiom 2. The space described by a motion while it is accelerated, is less than the space which is described in an equal time by the motion that is acquired by that acceleration continued uniformly.

Axiom 3. The space described by a retarded motion is less than the space which would have been described in the same time, if the motion had not been retarded, but had continued uniform from the beginning of the time.

Axiom 4. The space described by a motion while it is retarded, is greater than the space which is described in an equal time by the motion that remains after that retardation, continued uniformly.

From these axioms, general theorems concerning motion, of use in the doctrine of *Fluxions*, may be demonstrated. Thus when the spaces described by two variable motions are always equal, or in a given ratio, the velocities are always equal, or in the same given ratio; and conversely, when the velocities of two motions are always equal to each other, or in a given ratio, the spaces described by those motions in the same time are always equal, or in that given ratio; that when a space is always equal to the sum or difference of the spaces described by two other motions, the velocity of the first motion is always equal to the sum or difference of the velocities of the other motions; and conversely, that when a velocity is

always equal to the sum or difference of two other velocities, the space described by the first motion is always equal to the sum or difference of spaces described by these two other motions. See Mr. Maclaurin's *Treatise of Fluxions*, book i. chap. 1.

The main point in the method of *fluxions*, is to obtain the *fluxion* of the rectangle, or product of two indeterminate quantities, since from thence may be derived rules for all other products and powers, be the coefficients, or the indices what they will: integers or fractions, rational or surd; according to the manner of Sir Isaac Newton, in the second lemma of his second book of *Principles*.

Mr. Maclaurin has therefore been very full in establishing this point, and after what he has said, we presume that no reasonable objection can lie either against the clearness and distinctness of the notion of *fluxions*, or against the truth of the principles, or accuracy of the demonstrations by which their measures are determined. We cannot here insert his demonstration at length; but as many readers may, perhaps, be desirous of seeing the argument contracted into a narrow compass, we shall here give a summary of it, from the *Philosophical Transactions*, N^o 488, p. 331, or Martyn's *Abridg.* vol. viii. p. 31, &c.

A triangle that has two of its sides given in position, is supposed to be generated by an ordinate moving parallel to itself along the base. When the base increases uniformly, the triangle increases with an accelerated motion, because its successive increments are *trapezoids*, that continually increase; therefore if the motion with which the triangle flows, was continued uniformly from any term for a given time, a less space would be described by it, than the increment of the triangle, which is actually generated in that time by axiom 1. but a greater space than the increment which was actually generated in an equal time preceding that term, by axiom 2. And hence it is demonstrated, that the *fluxion* of the triangle is accurately measured by the rectangle contained by the corresponding ordinate of the triangle, and the right line which measures the *fluxion* of the base. The increment which the triangle acquires in any time, is resolved into two parts; that which is generated in consequence of the motion with which the triangle flows at the beginning of the time, and that which is generated in consequence of the acceleration of this motion for the same time. The latter is justly neglected in measuring that motion (for the *fluxion* of the triangle at that term) but may serve for measuring its acceleration, or the second *fluxion* of the triangle. The motion with which the triangle flows, is similar to that of a body descending in free spaces by an uniform gravity, the velocity of which, at any term of the time, is not to be measured by the space described by the body in a given time, either before or after that term, because the motion continually increases, but by a mean between these spaces.

When the sides of a rectangle increase or decrease with uniform motions, it may be always considered as the sum or difference of a triangle and trapezium; and this *fluxion* is derived from the last proposition. If the sides increase with uniform motions, the rectangle increases with an accelerated motion; and in measuring this motion at any term of the time, a part of that increment of the rectangle that may be determined, is rejected, as generated in consequence of the acceleration of that motion.

Those who have well understood what precedes, will not be at a loss to conceive, that the *fluxion* of a curvilinear area, whether generated by an ordinate moving parallel to itself, or by a radius revolving round a given centre, may be determined by demonstrations of the same kind. When the ordinates of the figure increase, the increment of the area may be resolved in like manner into two parts, one of which only is to be retained in measuring the *fluxion* of the area, the other being rejected as generated in consequence of the acceleration of the motion with which the figure flows.

What has been hitherto said will set the difference between the notion of *fluxions* and that of infinitesimals, in a clear light. *Fluxions* may always be represented by finite quantities. The supposition of an infinitely little magnitude is too bold a postulation for such a science as geometry. Nor have authors accounted explicitly for the truth and perfect accuracy of the conclusions derived from this consideration. When they determine what is called the *difference*, but more accurately the *fluxion* of a quantity, they tell us they reject certain parts of the increments, because they become infinitely less than the other parts. But this is no proper reason, not only because a proof of this nature may leave some doubt as to the accuracy of the conclusion, but because it may be demonstrated that these parts ought to be neglected by them

at any rate, or that it would be an error to retain them. If an accountant, that pretends to a scrupulous exactness, should tell us, he had neglected certain articles, because he found them to be of small importance; and it should appear that they ought not to have been taken into consideration by him on that occasion, but belong to a different account, we should approve his conclusions as accurate, but not his reason. See Maclaurin's *Treatise of Fluxions* in the preface, and book i. chap. 12, where the method of *infinitesimals* is expressly treated of. Mr. Maclaurin in the first part of his treatise considers *fluxions* in a merely geometrical form, and has demonstrated the rules of the method with all possible accuracy and rigour; but as the great improvements made by this doctrine are chiefly to be ascribed to the facility, conciseness, and great extent of the methods of computation, or the algebraic part, it is necessary to add some account of these methods also.

Any quantities produced from each other by an algebraic operation, or whose relation is expressed by an algebraic form, being supposed to increase or decrease together, some will be found to increase or decrease by greater differences, or at a greater rate, others by less differences, or at a less rate; and while some are supposed to increase or decrease at one constant rate by equal successive differences, others increase or decrease by differences that are always varying. These rates of increase or decrease may be determined by comparing the velocities of points that always describe lines proportional to the quantities as before mentioned, but they may also be determined without having recourse to such suppositions, by a just reasoning from the simultaneous increments or decrements themselves.

When a quantity A increases by differences equal to a , $2A$ increases by differences equal to $2a$, and manifestly increases or decreases at a greater rate than A in the proportion of $2a$ to a or 2 to 1 ; and if m and n be invariable, $\frac{m}{n}A$ increases or decreases by differences equal to

$\frac{m}{n}a$, and therefore at a greater or less rate than A in proportion as $\frac{m}{n}$ is greater or less than a , or m is greater or less than n .

This seems to be easily conceived, without having recourse to any other considerations, than the relation of the differences by which the quantities increase or decrease. In order therefore to avoid figurative expressions in the algebraic part, it will be proper to substitute in the place of the definition and axioms before mentioned, others that are rather of a more general import, but are perfectly consistent with them. Thus, *Fluxions of quantities are any measures of their respective rates of increase or decrease while they vary or flow together.*

There can be no difficulty in determining those measures when the quantities increase or decrease by successive differences, that are always in the same invariable proportion to each other. While A by increasing becomes equal to $A + a$, or by decreasing equal to $A - a$, $2A$ becomes equal to $2A + 2a$, or to $2A - 2a$; and $2A$ increases or decreases at a greater rate than A in the proportion of $2a$ to a ; so the *fluxion* of $2A$ being supposed equal to a , the *fluxion* of A must be equal to $\frac{a}{2}$.

In the same manner the *fluxion* of $\frac{m}{n} \times A$ (or of $\frac{m}{n} \times$

$A \pm a$, supposing m , n , and a to be invariable) is $\frac{m}{n} \times a$; and since m may be to n in any assignable ratio, a quantity may be always assigned that shall increase or decrease, at a greater or less rate than A in any proportion, or that shall have its *fluxion* greater or less than the *fluxion* of A in any ratio. In such cases, the ratio of the *fluxions* and that of the differences, by which the quantities increase or decrease, are the same.

But while A is supposed to increase at a constant rate by any equal successive differences, if B increase or decrease by differences that are always varying, B cannot be said to increase or decrease at any one constant rate; and it is not so obvious how the *fluxion* of A being supposed equal to its increment a , the variable *fluxion* of B is to be determined. It cannot be supposed that the *fluxions* and differences are always in the same proportion in this case; but it is evident, that if B increase by differences that are always greater than the equal successive differences by which $\frac{m}{n} \times A$ increases, it cannot increase

at a less rate than $\frac{m}{n} \times A$; and it cannot increase at a greater rate than $\frac{m}{n} \times A$, while its successive differences

always less than those of $\frac{m}{n} \times A$. The *fluxion* of A , being still represented by u , the *fluxion* of B therefore cannot be less than $\frac{m}{n} \times u$ in the former case, or greater

than $\frac{m}{n} \times u$ in the latter. The following propositions are consequences of this, and will enable us to determine at what rate B increases, when its relation to A is known.

The successive values of the root A being represented by $A - e, A, A + e$, &c. which increase by any constant difference e , let the corresponding values of any quantity produced from A , by any algebraic operation (or that has a dependence upon it so as to vary with it) be $B - b, B, B + b$, &c. Then, if the successive differences b, b , &c. of the latter quantity always increase, how small soever e may be, then B cannot be said to increase at so great a rate as a quantity that increases uniformly by equal successive differences greater than b , or at so small a rate as a quantity that increases uniformly by equal successive differences less than b . In like manner, if the relation of the quantities is such, that the successive differences b, b , &c. continually decrease; then B cannot be said to increase at the same rate as a quantity that increases uniformly by equal successive differences greater than b , or less than b .

Therefore the *fluxion* of A being supposed equal to the increment e , the *fluxion* of B cannot be greater than b or less than b , when the successive differences b, b , &c. continually increase; and cannot be greater than b or less than b , when these successive differences always decrease.

In the same manner, if the latter quantity decrease while the former increases, and its successive values be $B - b, B - b$, &c. then if the decrements b, b , &c. continually increase, B cannot be said to decrease at so great a rate as a quantity that decreases uniformly by equal successive differences greater than b , or at so small a rate as a quantity that decreases uniformly by equal successive differences less than b . Therefore in this case the *fluxion* of A being supposed equal to e , the *fluxion* of B cannot be greater than b or less than b . And in the same manner if the successive decrements b, b , &c. always decrease, the *fluxion* of B cannot be greater than b , or less than b . Vide Maclaurin's Flux. book II. chap. I. tom. II. p. 579, seq.

As the *fluxions* of quantities are any measures of the respective rates, according to which they increase or decrease; so it is of no importance how great or small those measures are, if they be in the just proportion or relation to each other. Therefore if the *fluxions* of A and B may be supposed equal to a and b respectively, they may be likewise supposed equal to $\frac{1}{2}a$ and $\frac{1}{2}b$, or to $\frac{m}{n}a$ and $\frac{mb}{n}$.

Prop. I. The *fluxion* of the root A being supposed equal to u , the *fluxion* of the square AA will be equal to $2 \times u \times A$. To demonstrate this, let the successive values of the root be $A - u, A, A + u$, and the corresponding values of the square will be $A^2 - 2Au + u^2, A^2, A^2 + 2Au + u^2$, which increase by the differences $2A - u, 2A, 2A + u$, &c. and because those differences increase, it follows from what has been said, that if the *fluxion* of A be represented by u , the *fluxion* of AA cannot be represented by a quantity that is greater than $2A + u$, or less than $2A - u$. This being premised, suppose, as in the proposition, that the *fluxion* of A is equal to u ; and if the *fluxion* of AA be not equal to $2 \times A \times u$, let it first be greater than $2 \times A \times u$ in any ratio, as that of $2A + u$ to $2A$, and consequently equal to $2A + u$. Suppose now that u is any increment of A less than u ; and because u is to u as $2A + u$ is to $2A + u$, it follows, that if the *fluxion* of A should be represented by u , the *fluxion* of AA would be represented by $2A + u$, which is greater than $2A + u$. But it has been shewn, that if the *fluxion* of A be represented by u , the *fluxion* of AA cannot be represented by a quantity greater than $2A + u$. And these being contradictory, it follows, that the *fluxion* of A being equal to u , the *fluxion* of AA cannot be greater than $2A + u$. If the *fluxion* of A can be less than $2A + u$, when the *fluxion* of A is supposed equal to u , let it be less in any ratio of $2A - u$ to $2A$, and therefore equal to $2A - u$. Then because u is to u as $2A - u$ is to $2A - u$, which is less than $2A - u$, (u being supposed less than u , as before) it follows, that if the *fluxion* of A was represented by u , the *fluxion* of AA would be represented by a quantity less than $2A - u$, against what has been shewn. Therefore the *fluxion* of A being supposed equal to u , the *fluxion* of AA must be equal to $2A \times u$.

The *fluxions* of A and B being supposed equal to a and b , respectively, the *fluxion* of $A + B$ will be $a + b$, the *fluxion* of $A + B^2$, or of $AA + 2AB + BB$, will be $2 \times A \times a + b$, or $2Aa + 2Bb + 2Aa$, by the last article. The *fluxion* of $AA + BB$ is $2Aa + 2Bb$, by the same; consequently the *fluxion* of $2AB$ is $2Aa + 2Bb$; and the *fluxion* of AB is $Ba + Ab$. Hence if P be equal to AB , and the *fluxion* of P be p , then p will be equal to $Ba + Ab$, and dividing by P , or AB , we find $\frac{p}{P} = \frac{a}{A} + \frac{b}{B}$. If $Q = \frac{A}{B}$, and q be the *fluxion*

of Q , then $QB = A$, $\frac{q}{Q} + \frac{a}{B} = \frac{a}{A}$, or $\frac{q}{Q} = \frac{a}{A} - \frac{b}{B}$; and consequently $q = \frac{Qa}{B} - \frac{Qb}{B} = \frac{a}{B} - \frac{Ab}{BB}$, or $aB - Ab$.

When any of the quantities decrease, its *fluxion* is to be considered as negative.

The rule for finding the *fluxion* of a power is usually deduced from the binomial theorem of Sir Isaac Newton. But as this theorem, though easily found by induction, is not so easy to be demonstrated, it is proper to proceed upon a principle, the truth of which may be shewn from the first algebraic elements, with more facility and perspicuity. This principle is, that if n be any integer number, and the sum of the terms $E - F, E - F, E - F, E - F$, &c. continued till their number be equal to n , be multiplied by $E - F$, the product will be $E^n - F^n$. For the terms being formed by subtracting continually unity from the index of E , and adding it to the index of F , the last term will be F^n . The product of the sum of the terms multiplied by E will be $E^n + E^{n-1} + E^{n-2} + F + F^2 + F^3 + F^4 + F^5 + F^6 + F^7 + F^8 + F^9 + F^{10} + F^{11} + F^{12} + F^{13} + F^{14} + F^{15} + F^{16} + F^{17} + F^{18} + F^{19} + F^{20} + F^{21} + F^{22} + F^{23} + F^{24} + F^{25} + F^{26} + F^{27} + F^{28} + F^{29} + F^{30} + F^{31} + F^{32} + F^{33} + F^{34} + F^{35} + F^{36} + F^{37} + F^{38} + F^{39} + F^{40} + F^{41} + F^{42} + F^{43} + F^{44} + F^{45} + F^{46} + F^{47} + F^{48} + F^{49} + F^{50} + F^{51} + F^{52} + F^{53} + F^{54} + F^{55} + F^{56} + F^{57} + F^{58} + F^{59} + F^{60} + F^{61} + F^{62} + F^{63} + F^{64} + F^{65} + F^{66} + F^{67} + F^{68} + F^{69} + F^{70} + F^{71} + F^{72} + F^{73} + F^{74} + F^{75} + F^{76} + F^{77} + F^{78} + F^{79} + F^{80} + F^{81} + F^{82} + F^{83} + F^{84} + F^{85} + F^{86} + F^{87} + F^{88} + F^{89} + F^{90} + F^{91} + F^{92} + F^{93} + F^{94} + F^{95} + F^{96} + F^{97} + F^{98} + F^{99} + F^{100}$.

When n is any integer positive number, the root A being supposed to increase by any equal successive differences, the successive differences of the power A^n will continually increase. For let $A - u, A, A + u$ be any successive values of the root, and $A^n - u^n, A^n, A^n + u^n$ will be the corresponding values of the power. But $A^n + u^n - A^n$ is greater than $nA^{n-1}u$; as appears by substituting in the last paragraph $A + u$ for A , and F for E , and for $E - F$. In like manner, $nA^{n-1}u$ is greater than $A^n - A^{n-1}u$. Therefore $A^n + u^n - A^n$ is greater than $A^n - A^{n-1}u$, and the successive differences of the power continually increase.

Prop. II. The *fluxion* of the root A being supposed equal to u , the *fluxion* of the power A^n will be $nA^{n-1}u$.

For if the *fluxion* of A can be greater than $nA^{n-1}u$, let the excess be equal to any quantity r , suppose r equal to

the excess of $\sqrt[n]{A^n + r}$ above A , and consequently

$A^n + r = A^n + \frac{r}{nA^{n-1}}$. Then $nA^{n-1}u + r$ will be

equal to $nA^{n-1}u + r$, the *fluxion* of A^n . Let u be any increment of A less than u ; and because u is to u as $nA^{n-1}u + r$ to $nA^{n-1}u + r$, it follows (from what has been said) that if the *fluxion* of A should be represented by the increment u , the *fluxion* of A^n would be represented by $nA^{n-1}u + r$, which is greater than $nA^{n-1}u$.

And this last is itself greater than $A^n + r - A^n$. But when the successive values of the root are $A - u, A, A + u$, those of the power are $A^n - u^n, A^n, A^n + u^n$, the successive differences of which continually increase; consequently if the *fluxion* of A be represented by u , the *fluxion* of A^n cannot be represented by a quantity greater than $A^n + u^n - A^n$, or less than $A^n - u^n - A^n$. And these being contradictory, it follows, that when the *fluxion* of A is supposed equal to u , the *fluxion* of A^n cannot be greater than $nA^{n-1}u$. If it can be less than $nA^{n-1}u$, let it be equal to $nA^{n-1}u - r$, or (by supposing $r = A^n - A^{n-1}u$)

$\sqrt[n]{A^n - r} = A - \frac{r}{nA^{n-1}}$. Then $nA^{n-1}u - r$ will be

equal to $nA^{n-1}u - r$, the *fluxion* of A^n . Let u be any increment of A less than u ; and because u is to u as $nA^{n-1}u - r$ to $nA^{n-1}u - r$, it follows (from what has been said) that if the *fluxion* of A should be represented by the increment u , the *fluxion* of A^n would be represented by $nA^{n-1}u - r$, which is less than $nA^{n-1}u$.

And this last is itself greater than $A^n - u^n - A^n$. But when the successive values of the root are $A - u, A, A + u$, those of the power are $A^n - u^n, A^n, A^n + u^n$, the successive differences of which continually increase; consequently if the *fluxion* of A be represented by u , the *fluxion* of A^n cannot be represented by a quantity greater than $A^n + u^n - A^n$, or less than $A^n - u^n - A^n$. And these being contradictory, it follows, that when the *fluxion* of A is supposed equal to u , the *fluxion* of A^n cannot be greater than $nA^{n-1}u$. If it can be less than $nA^{n-1}u$, let it be equal to $nA^{n-1}u - r$, or (by supposing $r = A^n - A^{n-1}u$)

$\sqrt[n]{A^n - r} = A - \frac{r}{nA^{n-1}}$. Then $nA^{n-1}u - r$ will be

equal to $nA^{n-1}u - r$, the *fluxion* of A^n . Let u be any increment of A less than u ; and because u is to u as $nA^{n-1}u - r$ to $nA^{n-1}u - r$, it follows (from what has been said) that if the *fluxion* of A should be represented by the increment u , the *fluxion* of A^n would be represented by $nA^{n-1}u - r$, which is less than $nA^{n-1}u$.

And this last is itself greater than $A^n - u^n - A^n$. But when the successive values of the root are $A - u, A, A + u$, those of the power are $A^n - u^n, A^n, A^n + u^n$, the successive differences of which continually increase; consequently if the *fluxion* of A be represented by u , the *fluxion* of A^n cannot be represented by a quantity greater than $A^n + u^n - A^n$, or less than $A^n - u^n - A^n$. And these being contradictory, it follows, that when the *fluxion* of A is supposed equal to u , the *fluxion* of A^n cannot be greater than $nA^{n-1}u$. If it can be less than $nA^{n-1}u$, let it be equal to $nA^{n-1}u - r$, or (by supposing $r = A^n - A^{n-1}u$)

$\sqrt[n]{A^n - r} = A - \frac{r}{nA^{n-1}}$. Then $nA^{n-1}u - r$ will be

equal to $nA^{n-1}u - r$, the *fluxion* of A^n . Let u be any increment of A less than u ; and because u is to u as $nA^{n-1}u - r$ to $nA^{n-1}u - r$, it follows (from what has been said) that if the *fluxion* of A should be represented by the increment u , the *fluxion* of A^n would be represented by $nA^{n-1}u - r$, which is less than $nA^{n-1}u$.

posed

posed less than a , if the *fluxion* of A was represented by u , the *fluxion* of A^m would be represented by $m \times A^{m-1} \times u$, which is less than $m \times A^{m-1} \times u$ (because we suppose u to be less than a) and therefore less than $A^m - A^{m-1}$. But this is repugnant to what has been demonstrated. Therefore the *fluxion* of A being supposed equal to a , the *fluxion* of A^m must be equal to $m \times A^{m-1}$. Prop. III. The *fluxion* of A being supposed equal to a , the *fluxion* of A^m will be $\frac{m}{n} \times a \times A^{m-n}$.

First, let the exponent $\frac{m}{n}$ be any positive fraction what-

soever, suppose $A^{\frac{m}{n}} = K$; consequently $A^m = K^n$; and the *fluxion* of K being supposed equal to l , $m \times A^{m-1} = n \times K^{n-1} \times l$, and l or the *fluxion* of $A^{\frac{m}{n}}$ will be equal to $\frac{m}{n} \times A^{m-n} = \frac{m}{n} \times K = \frac{m}{n} \times a \times A^{m-n}$. When $\frac{m}{n}$ is negative, let it be equal to $-r$; and suppose $A^{-r} = K$, or $r = A^{-r} K$, then taking the *fluxion*, $r \times A^{-r-1} \times K + A^{-r} \times l = 0$, and $l = -\frac{r \times A^{-r-1} \times K}{A^{-r}} = -r \times A^{-r-1} \times a \times A^{m-n} = -\frac{r}{n} \times a \times A^{m-n}$.

Prop. IV. Supposing P to be the product of any factors A, B, C, D, E , &c. and the *fluxions* of P, A, B, C , &c.

respectively equal to p, a, b , &c. then will $\frac{P}{P} = \frac{a}{A} + \frac{b}{B} + \frac{c}{C} + \frac{d}{D} + \frac{e}{E}$, &c.

Let Q be equal to the product of all the factors of P , the first A excepted, that is, suppose $P = A \times Q$. Suppose R equal to the product of all the factors, the first two, A and B , excepted; that is, let $P = A \times B \times R$, or $Q = B \times R$. In the same manner let $R = C \times S$, $S = D \times T$, and so on. Then the *fluxion* of Q, R, S, T , &c. being supposed respectively equal to q, r, s, t , &c. it follows that $\frac{P}{P} = \frac{a}{A} + \frac{q}{Q}$, (because $\frac{Q}{Q} = \frac{b}{B} + \frac{r}{R}$) $\frac{a}{A} + \frac{b}{B} + \frac{r}{R} + \frac{q}{Q}$ = (because $\frac{R}{R} = \frac{c}{C} + \frac{s}{S}$) $\frac{a}{A} + \frac{b}{B} + \frac{c}{C} + \frac{s}{S} + \frac{q}{Q}$ = (because $\frac{S}{S} = \frac{d}{D} + \frac{t}{T}$) $\frac{a}{A} + \frac{b}{B} + \frac{c}{C} + \frac{d}{D} + \frac{t}{T} + \frac{q}{Q}$, and so on. Therefore $\frac{P}{P}$ is equal to the sum of the quotients, when the *fluxion* of each factor is divided by the factor itself.

If the factors be supposed equal to each other, and their number be equal to n , then $P = A^n$, and by the last proposition $\frac{P}{P} = \frac{n \times a}{A}$; consequently $p = \frac{n \times P \times a}{A} = n \times a \times A^{n-1}$, as was before demonstrated.

Prop. V. If $P = \frac{f \times g \times h \times i \times k}{l \times m \times n \times o \times p}$, &c. and the *fluxions* of the respective quantities be expressed by the small letters p, a, b, c, e , &c. as before, then $\frac{P}{P} = \frac{a}{A} + \frac{b}{B} + \frac{c}{C} - \frac{d}{D} - \frac{e}{E} - \frac{f}{F} - \frac{g}{G} - \frac{h}{H} - \frac{i}{I} - \frac{k}{K} - \frac{l}{L} - \frac{m}{M} - \frac{n}{N} - \frac{o}{O} - \frac{p}{P}$, &c.

For $PKLM$, &c. = ABC , &c. and $\frac{P}{P} = \frac{a}{A} + \frac{b}{B} + \frac{c}{C} + \frac{d}{D} + \frac{e}{E} + \frac{f}{F} + \frac{g}{G} + \frac{h}{H} + \frac{i}{I} + \frac{k}{K} + \frac{l}{L} + \frac{m}{M} + \frac{n}{N} + \frac{o}{O} + \frac{p}{P}$, &c. whence by transposition $\frac{P}{P} = \frac{a}{A} + \frac{b}{B} + \frac{c}{C} - \frac{d}{D} - \frac{e}{E} - \frac{f}{F} - \frac{g}{G} - \frac{h}{H} - \frac{i}{I} - \frac{k}{K} - \frac{l}{L} - \frac{m}{M} - \frac{n}{N} - \frac{o}{O} - \frac{p}{P}$, &c. Maclaurin, libid.

The notation we have hitherto used is the same as Sir Isaac Newton's, in the second lemma of the second book of his Principles. But it is generally more convenient to distinguish *fluxions* from other algebraic expressions, and in such manner, that the second and higher *fluxions* may be represented so as to preserve the original fluent in view. Hence Sir Isaac Newton, in his last method, represented variable or flowing quantities by the final letters of the alphabet, as x, y, z , their first, second, &c. *fluxions*, respectively by $\dot{x}, \ddot{x}, \ddot{\dot{x}}$, &c. But as this doctrine has been contended and reprobated by the author of the Analyst, as inconceivable and sophistical, we thought it proper more fully to explain and demonstrate the principles thereof, from Mr. Maclaurin's excellent treatise on this subject.

It is to be observed, that the *fluxions* of powers are commonly delivered in an algebraic form; but this is not necessary. The same may be done geometrically, by supposing a series of lines in geometric progression, the first term of which is invariable. Then if the second term be supposed to increase uniformly, all the subsequent

terms will increase with an accelerated motion. The velocities of the points that describe those lines being compared, it may be demonstrated from common geometry, that the *fluxions* of any two terms are in a ratio compounded of the ratio of those terms, and of the ratio of the numbers that express how many terms precede them respectively, in the progression. Thus, if A, B, C, D, E , &c. represent any lines in geometrical progression, the first term (A) of which is invariable, then will the *fluxion*, for instance, of E be to the *fluxion* of D as $4E$ is to $3D$, and the *fluxion* of E will be to the *fluxion* of B as $4E$ is to $2B$. The analogy between powers in algebra and lines in geometric progression, is sufficiently known. Thus A being invariable may be called unity or 1; let $B = x$, then will $C = x^2, D = x^3, E = x^4$, &c. and consequently, the *fluxion* of E or x^4 , will be to the *fluxion* of B or x , as $4x^4$ is to x , or as $4x^3$ is to 1. Therefore if the *fluxion* of x be expressed by $\dot{x}$, the *fluxion* of x^4 will be expressed by $4x^3 \dot{x}$, agreeable to the common algebraic method of explication. Vide Mr. Maclaurin's *Flux*, book 1, chap. 6. See also the *Present State of the Rep.* of Let. Oct. 1735, p. 248, 249, &c.

If the *fluxion* of B , or the second term of the progression be invariable, every term of the progression will have *fluxions* of as many degrees, as there are terms that precede it in the progression. And the increment of any term generated in a given time may be resolved into as many parts, as it has *fluxions* of different orders; and each part may be conceived to be generated, in consequence of its respective *fluxion*. Hence *fluxions* of all orders may be illustrated and measured.

As to the higher orders of *fluxion*, it is to be observed, that when a motion is accelerated or retarded continually, the velocity may still be considered as a variable or flowing quantity, and may be represented by a line that increases or decreases continually. When a velocity increases uniformly so as to acquire equal increments in equal times, its *fluxion* is measured by the increment which is generated in any given time. In this case, the velocity is represented by a line that is described by an uniform motion; and its *fluxion*, by the constant velocity of the point that describes the line, or by the space which this point describes in a given time. When a velocity is not accelerated uniformly, but acquires increments in equal times, that continually increase or decrease, then its *fluxion* at any term of the time is not measured by the increment, which it actually acquires, but by that which it would have acquired, if its acceleration had been continued uniformly from that term for a given time. And in the same manner, when a motion is retarded continually, the quantity by which it would be diminished in a given time, if this retardation was continued uniformly for any term, measures its *fluxion* at that term. While the point M describes the line EE , let the point Q describe the line II , so that IQ may be always equal to the space that would be described by the motion of M , if it was continued uniformly for a given time. Then IQ shall always represent the velocity of M , and the velocity of the

point Q shall represent the *fluxion* of the velocity of M , which therefore is measured, at any term of the time by the space which would be described by Q , with its motion at that term continued uniformly for a given time. The velocity of M is the *fluxion* of EM ; and therefore the velocity of Q represents the *fluxion* of the *fluxion* of EM . See the beginning of this article. Thus, when a *fluxion* of a quantity is variable, it may be considered itself as a fluent, and may have its *fluxion*, which is called the *second fluxion* of that quantity. This may also have its *fluxion*, which is called the *third fluxion* of the first fluent; and motions may be easily conceived to vary in such a manner, as to give ground for admitting second *fluxions*, and those of any higher order. And as the first *fluxion* of a variable quantity, at any term of the time, is measured by the increment, or decrement, which would be produced, if the generating motion was continued uniformly from that term, for a given time; so its second *fluxion* may be measured by twice the difference betwixt its increment, or decrement, and that which would be produced, if the acceleration, or retardation, of the generating motion was continued uniformly from that term for the same time. Maclaurin, lib. cit. book 1, chap. 1, § 70, 75, and chap. 5, 6.

See a farther illustration of second and third *fluxions*, in the same author (chap. 3, and 4.) deduced from the consideration of the *fluxion* of solids. The author of the Analyst has represented the notions of second and third *fluxions*, as inextricable mysteries; and indeed,

indeed, when some speak of the velocities of velocities, &c. it is not easy to lay what they mean. But it is to be observed, that the first *fluxion* of any fluent is not the velocity of that fluent, but the velocity of the motion by which the fluent is conceived to be generated. And in like manner, the second *fluxion* of that fluent is not the velocity of the velocity of this fluent, but the velocity of the motion by which the quantity is generated that always represents its first *fluxion*, and so of the rest.

When the *fluxion* of a quantity is variable it may be considered as a fluent; and its *fluxion*, which is the second *fluxion* of the proposed quantity, may be determined by the preceding propositions. Thus the *fluxion* of A being supposed equal to a , the *fluxion* of AA is $2Aa$; and if A be supposed to increase at an uniform rate, or its *fluxion* a to be invariable, $2Aa$ will increase by equal successive differences; consequently its *fluxion*, or the second *fluxion* of AA , will be equal to any of these differences, as to $2 \times Aa + a - 2Aa$, or $2da$. If a be variable, let its *fluxion* be equal to α , and the *fluxion* of $2Aa$ (or second *fluxion* of AA) will be $2\alpha a + 2A\alpha$. In the same manner the *fluxion* of A being constant, the *fluxion* of A^n is $nA^{n-1}a$, or the second *fluxion* of A^n is $n \times n-1 \times A^{n-2}a^2$, or $n \times n-1 \times A^{n-2} \alpha a$; the *fluxion* of this, or third *fluxion* of A^n , is $n \times n-1 \times n-2 \times A^{n-3} \alpha^2$. And the *fluxion* of A^n of any order denoted by m , is $n \times n-1 \times n-2 \times \dots \times n-m+1 \times A^{n-m} \alpha^m$, where the factors in the coefficient are to be continued till their number be equal to m . When n is any integer positive number, the *fluxion* A^n , of the order n , is invariable and equal to $n \times n-1 \times n-2 \times \dots \times n-m+1 \times A^{n-m} \alpha^m$. The quantities that represent these *fluxions* of A^n depend on a , which represent the *fluxion* of A . When A remains of the same value, the first *fluxion* of A^n is greater or less in the same proportion, as a is supposed to be greater or less; the second *fluxion* of A^n is in the duplicate ratio of a ; and its *fluxion* of the order m is as α^m . If a be variable, but n the *fluxion* of a , or the second *fluxion* of A , be constant, then the fourth *fluxion* of AA will be constant and equal to $62a$; for we found, that the second *fluxion* of AA was $2Aa + 2A\alpha$; the *fluxion* of which is $4a\alpha + 2a\alpha$, or $6a\alpha$; and the *fluxion* of this is $62a$. In like manner, the sixth *fluxion* of AA will be constant in this case, and equal to 9021 .

The second differences of any quantity B are the successive differences of its first differences; and as the *fluxion* B increases when its successive differences increase; so its second *fluxion*, or its *fluxion* of any higher order increase, when its second or higher differences increase. If we arrive at differences of any order that are constant, the *fluxion* of the same order is constant, and is expressed by that difference. Thus when A is supposed to increase by constant differences equal to a , and its *fluxion* is supposed equal to a , the second difference of AA (or $A^2 + A^2 + A^2 - A^2$) is $2a$, which is likewise its second *fluxion*; and the third difference of A^3 is $6a^3$, which is its third *fluxion*. When n is any integer and positive number, the *fluxion* of A^n of the order n is equal to the *fluxion* of any of its first differences of the order $n-2$, and so on. For the *fluxion* of $A^2 + A^2 - A^2$ (one of the first differences of A^3) of the order $n-1$ is $n \times n-1 \times A^{n-2}a$, &c. $\times A^2 + A^2 - A^2$ of the order $n-1$ is $n \times n-1 \times A^{n-2}a$, &c. $\times A^2$, where the coefficients are supposed to be continued till their number be $n-1$, so that the last must be 2. And this we found to be the *fluxion* of A^n of the order n in the preceding paragraph. In the same manner the *fluxion* of $A^2 + A^2 - A^2$ (the second difference of A^3) of the order $n-2$, is equal to the *fluxion* of $A^2 + A^2 - A^2$ of the order $n-1$, and consequently equal to the *fluxion* of A^n of the order n . These *fluxions* are invariable and equal to the last or invariable differences. But in other cases the *fluxions* of A^n of any order are less than its subsequent differences of the same order, but greater than the preceding differences, as before mentioned. Maclaurin's *Flux.* art. 720, seq.

By supposing one of the variable quantities to flow uniformly, it will have no second or higher *fluxions*, and the higher *fluxions* depending on it will be expressed in a more simple manner. Thus the *fluxion* of x being supposed constant, the first *fluxion* of x^n being $n \times x^{n-1}a$, its second *fluxion* will be $n \times n-1 \times x^{n-2}a^2$, and its *fluxion* of any order m will be $n \times n-1 \times n-2 \times \dots \times n-m+1 \times x^{n-m} \alpha^m$, where the factors in the coefficient are to be continued till their number be equal to m .

The second or higher *fluxions* of quantities may be found by particular theorems (without computing those of the preceding orders) as may be seen by the last example.

See farther in Maclaurin's *Fluxions*, art. 731. See Rule 10. in the beginning of this article.

The use of the direct method of *fluxions*, see specified under the articles EVOLUTES, INFLECTION, MAXIMS and MINIMS, and TANGENTS.

Those of the inverse method, see under QUADRATURE and RECTIFICATION of curves.

FLY, *Motus*, in Natural History. The account of the several species, genera, and classes of *flies*, is no small part of the natural history of insects. The number of the species of *flies* exceed perhaps even that of the butterfly; but the *flies* are in general small, though there are some, as the libellæ, whose bodies are longer and larger than those of the largest butterflies. The cicadæ also belong to the *fly* class; and there are some of those, whose size exceeds that of the largest butterflies in the thickness of their bodies. The generality of *flies*, however, are much smaller than the butterfly class, and many of them are indeed so very small, as not easily to be distinguished.

Many of the *flies* are in their prior state hid from us, or detained among very disagreeable matters; it is in their winged state that they become an agreeable object of our researches, and it may be most proper, therefore, to begin their history in that state, occasionally descending to the others.

It is a common error to imagine, that the small *flies* one sees in the spring, will become larger in summer. This is wholly without foundation, since all the *flies*, like other insects which undergo a metamorphosis, become of their full bigness, as soon as they arrive at the *fly* state, and never grow afterwards.

The general and obvious character of *flies*, by which they are distinguished from other winged insects, is their having transparent wings, and never having on them any of that powder which is found on the wings of butterflies, and having no cases or covers for them. They are, by this plain character of their transparent and naked wings, distinguished from the butterfly, the beetle, the grasshopper, and other classes of winged insects.

The parts of *flies* are the head, the CORCELLET, and the body. To the corcellet the wings are affixed, and in the body are contained the stomach, intestines, the parts of generation, and a great many of the tracheæ. The head in *flies* is usually joined to the corcellet by a very short neck, and can often turn on it as on a pivot. Some *flies* there are which have as it were two corcellets, one separated from the other; the first in this case is usually very small, and the wings are affixed to the second. The corcellet is the most prominent and rounded part of the insect; it is always the strongest part, and is frequently the thickest. The forcina leo and some water insects, are transformed into *flies* which have double corcellets, or corcellets divided into two.

The most obvious distinctions for the arrangement of *flies* into classes, is the number of their wings; some having only two, others four. And this is by plain and obvious division, that it is wonderful that the writers of natural history have not long since fallen into it, nay, many of them have often omitted to tell us the number of wings of the species they describe.

The first general division of *flies* is therefore into that of the two-winged and four-winged kind. A very slight observation is generally sufficient to determine to which of these divisions a *fly* belongs; but if we afterwards examine a *fly* with more attention, and take into consideration the organs by which it takes its nourishment, one may observe, that some of them are able to thrust out that organ to a considerable distance from their head, and that this organ, which, while in a state of rest, is folded up or shortened, or curved about, or laid closely down, when the creature wants to use it, is unfolded, lengthened, extended, or raised. This organ is what naturalists call the trunk of an insect, but there are many other *flies* which have no trunk; these have no other than an opening, serving for a mouth, surrounded with lips and with some other parts. This sort of opening, from its situation and figure, may very properly be called a mouth.

Some of these mouths have nothing analogous to teeth about them; but there are others which have teeth, fangs, or grinders, placed on the outside of the mouth, and moveable as in the caterpillars, with which the *flies* tear and destroy leaves, fruits, and flesh; finally, there are also some *flies* to which nature has allotted both a trunk and these organs.

These characters give us very naturally the distinction of four subordinate classes under the two former general ones.

The first contains those *flies* which have a trunk, and no teeth or fangs. The second contains those which have a mouth

mouth without any sensible teeth. The third, those which have a mouth furnished with teeth; and the fourth, those which have both trunks and teeth. Among the *flies* which have mouths furnished with teeth, some have them not only without, but within their mouths also.

All the two-winged *flies* belong to the first or second of these classes; the great blue *bell-fly*, the small *flies* that are so troublesome about our houses, and the gnats, are all of the first class, and have trunks and no teeth. The *spring-fly*, so common in gardens, and a sort of *fly* resembling the gnat kind, but much larger, are of the second class, and have mouths, but no sensible teeth.

The four-winged *flies* furnish us with great numbers to fill up the other two classes, left vacant by the former. All the bee-kind have a trunk and two teeth; all the wasp-kind have a mouth furnished with two teeth; and there are, beside these, several of the four-winged *flies* which belong to the second class; all the papilionaceous *flies*, produced of water, namely, are of this sort, as having a mouth without teeth. Several small four-winged *flies* are also of the first class; as the flying pucerons, and false pucerons, which have all trunks and no teeth; neither are the smaller species only of this class, since the cicada also belongs to it.

A fifth class may, however, be also established, though the species of it are only few, their being only two kinds of *flies* of it; this is, of those which have their head serving the office, or made in the form of a trunk. The *flies* of this kind have very long heads, which, like those of birds, terminate in a sort of beak; this, however, in the *fly*-kind, is never opened except at the end; or, in other words, these *flies* have heads, which are lengthened out into the resemblance of a bill, or figure of a trunk, but which is stiff, and cannot change its figure, nor alter its position, otherwise than by altering that of the whole head. At the end of this sort of trunk are placed the teeth or other organs, by which the creature gets in food. The first example of these heads is in the scorpion-*fly*, and a very beautiful *fly*, that is frequently seen skipping and leaping about flowers, is the other.

Under these general classes, subordinate ones are to be formed, from whatever besides is the most obvious and essential distinction among these little animals. The form of the body may very well afford us these distinctions. So that, in this respect, there are three subordinate classes under the five fore-mentioned classes: the first, of those *flies* whose bodies are short and broader than they are thick; the second, of those with long bodies; and the third, with bodies fastened to the coracel only by a fine filament; and under all these, the several genera are to be established from other lesser but constant and invariable differences; such as the differences of the manner of their carrying their wings, the figures of their antennae, the position of their trunks, and other similar differences. See *Tab. of Insects*, and *WINGS, TRUNKS, &c.*

FLIES, bodies of. The bodies of these insects are extremely different one from another, and even those whose general form makes them properly ranged in the same class, are not without their distinctions, by which they alone may be made to establish subordinate genera.

Among the *flies* which have short or ellipsoidal bodies, some have the body extremely flat and thin; such are those of the *flies* produced from the worms which devour the pucerons; and others have the hinder part of the body bent downward in form of a hook.

The extremity of the body in these animals is usually smaller than the adjoining parts. Yet there is a *fly* found in the nests of swallows, the extremity of whose body is larger than any other part of it; and not only the form of the body, but the differences of the filament, by which, in many genera, it is connected to the coracel, may furnish great matter for the distinctions of the subordinate genera.

The hinder part, or extremity of the body alone, may also afford great matter of distinction. Those *flies* which carry things in their tails, have in that alone a sufficient distinction.

Others there are which have organs placed there, which though we need not fear them, offer subject enough for our admiration; it is indeed the females alone who have occasion for these, and therefore the females alone are furnished with them.

Several of these instruments are a kind of auger or borer carried in a case or sheath. This sometimes has the form of a long tail to the insect, and its use is to pierce and bore the body, in which the creature is to deposit its eggs. Several of the female ichneumonians have this sort of long tail; and there are other insects which have a long and strong piercer, which however does not make a tail to their body, but is partly lodged either under their belly or in their body; of this kind are the cicadae, and others.

Other insects of this kind have a singular instrument lodged in this part of their body, which may properly be called a saw. They never flew this on examination, unless their bodies be pressed, and then we cannot but greatly admire the instrument itself, and the powers by which the creature moves it.

Other insects of this class carry behind one or more long slender filaments, which, in their form and structure, have some sort of resemblance to the antennae; and the uses of which are as little known to us, as those of the antennae. The genera of *flies* may very properly be distinguished by means of these: among the four-winged *flies*, the ephemerons, and many other species, have them; and among the two-winged kinds, the small *flies*, which is the male gall insect, furnishes us with an instance of them. See *Tab. of Insects*.

FLIES of water-worms. These, according to their several species, have some varieties in their manner of egress from their shell, at their leaving the nymph state for that of the perfect *fly*.

The long water-worms, composed of many rings, and with funnel-fashioned tails, made with an aperture for the admission of the air, surrounded with a multitude of hairs, retain, in their shell-state, so much of the time form which they had while living, that the one is not easy to be distinguished from the other. The nymph in each of these fills up only a small part of the cavity, and the *fly* in many of them is produced perfect in five or six days. At this time the parts of the nymph being thoroughly strengthened, it begins to shew the first signs of life in its attempt to open its prison.

To effect this, nature has so provided for the inclosed *fly*, that the head is but slightly joined to the second ring of the body; but the creature in this state, not being lodged in that part of the worm, can make no efforts against it; all its endeavours are bent to force a slit or opening in the second ring, like that in the back of the skin of a caterpillar that is going to change its skin, or like that of the butterfly chrysalis. The means the inclosed *fly* uses to this purpose, are the inflating and swelling its head, and then thrusting out the bladder from its anterior part, with which these *flies* are provided by nature in this stage of their lives, and for this only purpose. When this slit or crack is effected, the head of the worm is in some measure separated from the body, and the efforts of the *fly* to push itself forward, finish that separation, and leave an aperture of a proper size for the egress of the *fly*.

But the water, on the surface of which this change is effected, is a thing much to be dreaded, and indeed is often of fatal consequences to the new-born *fly*, since the *flies* produced of water-worms are at much afraid of this element, and are as easily drowned, as those produced from worms who spend their lives on dry land. The *flies* produced from this long water-worm are, however, in less danger, and less afraid of the water than many others; they advance slowly out of their shells in an horizontal direction, and, as soon as their fore-feet are at liberty, they boldly place them upon the water, as if upon dry land, and it serves as well for their support; and as their other parts get at liberty, they are gradually set upon the water too, and the creature there rests till its wings are unfolded, and all its parts have their proper form, and then takes its flight into its new element.

The *fly* produced from this long worm is of the short-bodied kind, and much of kin to the common great blue *bell-fly*. It has a fleshy trunk furnished with lips, and has no teeth; but though this *fly* is so far of the same class with that common species, it has enough to amply distinguish it in these separate characters. The first is, that this has its antennae formed of granulated filaments, whereas the other has them of the beaded kind: the wings of the *bell-fly* are not crossed upon the body, whereas those of this water-*fly* are; but what more than these distinguishes it from this, and indeed from all the other species of *flies*, is, that it has two oblong and slender bodies formed like pins, and polished as those, which are a little crooked, of a cutaneous structure, and are inserted in the upper part of the coracel of the *fly*, and directed towards its hinder part. See *Tab. of Insects*, N^o 40.

These prickles are hard, rigid, and immovable.

FLY, St. Mark. In *Natural History*, the name of a species of *fly*, which makes its first appearance every year about St. Mark's day, and is then seen in vast numbers; it is somewhat smaller than the large blue *bell-fly*, and has no trunk, but a mouth without teeth: notwithstanding this seemingly innocent organization, the creature does great mischief, and every gardener knows the effects of it at one time or other. These *flies* are found about fruit trees, and are always seen sitting upon the buttons of the leaves, and the flower-buds; and they do great mischief

in many kinds of trees, by sucking the juices of their tender parts, and either destroying them before they open, or at least rendering them very weak. Some tell us that these *flies* had originally a sting, but that the mischief they did, being very great, St. Mark deprived them of that offensive weapon for all generations: this is a story much believed by the country people in many of the Roman catholic kingdoms. The mouth is of the same figure with that of the tipula, or long leg, being composed of two membranous lateral lips, like the two valves of a shell-fish, which defend and cover two other fleshy lips within.

The male is easily distinguished from the female, by having a much larger head, and reticular eyes, much larger than her's, covering, in a manner, the whole head; besides these, it has also a cluster of three bright single eyes, placed in a triangle on the upper part of the head, and resembling the eyes of spiders. The wings of this *fly* are a little longer than its body, and crossed in such a manner, that one of them entirely covers the other, and even the body. This species has a singular manner of flying; they seem as if hanging in the air, their legs being suspended straight down from their body, and their length gives them an odd appearance. The common *fly* of this kind are of two species, one which is black, and another whose breast is a dusky red: but there are several other species so small as not to be distinctly seen without a microscope. They are all produced from worms, which are hatched from the eggs of the parent *fly*, deposited under the surface of the earth. They are found in great plenty in September and October in dung, into which they have crawled out of the earth for food.

If a piece of cow-dung, in which the worms of this St. Mark *fly* are, be preferred in a box, it will keep them alive the whole winter, and they will be found in the beginning of March, to be grown much larger than before and to be less hairy, their hairs being longer, and standing about nine on every ring. If this dung be laid on common earth at this time, they will crawl out of it into the ground, and transform themselves into the nymph state, from which they issue in the form of *flies* about the middle of April.

The manner of these *flies* leaving their worm state, to enter into that of the chrysalis or nymph, is worthy of observation. The worm turns in great disorder, and twists itself about several ways, till at length the skin cracks on the surface of the back: immediately upon this, there appears the anterior part of the nymph at the aperture, and this forces its way out by degrees, the head becomes of no farther use, and is left with the skin, and the nymph, by distending and contracting itself, at length makes its way wholly out of it, and then remains at rest till the *fly* issues out of it. The last transformation of this insect, or the appearance of the *fly* from the nymph, has nothing singular in it, but is performed in the same manner, with the same change as in other animals of the same kind.

FLY, *fly*. See FIRE-*fly*.

FLY, *fishy*. See FISHING-*fly*.

FLY, *flower*, in Natural History, the name of a small but very beautiful *fly*, described by Clusius. It is black, and has two sixery wings, two white eyes, seven yellow spots on the back, and a black one in the middle.

FLY, *harvest*. See HARVEST.

FLY, *humble-bee*. See HUMBLE-BEE-*fly*, and CULEX.

FLY, *lantern*. See LANTERN-*fly*.

FLY, *rose*. See ROSE.

FLY, *scorpion*. See SCORPION-*fly*.

FLY, *egg* of. See EGGS.

FLIES, *eye* of. See EYE.

FLIES, *leg* of. See LEG.

FLIES, *ring* of. See RING.

FLY, in Mechanics, a wheel with leaden weights at its ends, or rather a heavy wheel at right angles to the axis of a heavy windmill or roller, by means of which the force of the power is not only preferred, but equally distributed in all the parts of the revolution.

The *fly* may be applied to several sorts of engines, whether moved by men, horses, wind, or water, and is of great use in those parts of an engine which have a quick circular motion, and where the power or resistance acts unequally in the different parts of a revolution. In this case the *fly* becomes a moderator, making the motion of revolution almost every where equal.

The force of a *fly*, when joined with the screw, for stamping the image upon coins, may be calculated thus: suppose its two arms to be each fifteen inches long, measuring from the centre of the weight to the axis of the motion, and the weights to be fifty pounds each, and the diameter of the axis pressing upon the dye to be one inch; if every stroke be made in half a second, and the weights describe an half circumference, which will in

this case be of four feet, the velocity will at the instant of the stroke be at the rate of eight feet in a second, and therefore the momentum eight hundred; but the arms of the *fly* being at leavers, one brachium of which is fifteen inches long, whilst the other, viz. the semi-axis, is but half an inch, we must increase this force thirty times, which will give twenty-four thousand, an immense force, equal to that of a hundred pound weight falling a hundred and twenty feet, or near two seconds in time; or to that of a body of seven hundred and fifty pounds, falling 16 $\frac{1}{2}$ feet, or one second in time.

Some of these engines for coining crown-pieces have the arms of the *fly* five times as long, and the weights twice as heavy as those here mentioned, so that the effect is ten times greater. Desaguliers, Exper. Philosoph. vol. i. p. 245-330.

FLY, in the Sea-Language, that part of the mariner's compass on which the thirty-two winds are drawn, and to which the needle is fastened underneath.

FLY of an *eye*, is the breadth or extent from the flax to the extremity or edge that flutters loose in the wind.

Let *FLY the sheet*, at sea, a word of command, in case of a puff of wind, lest the ship should overset, or spend her top sails and masts, to have the sheet go a-main, and then the sail will hold no wind.

FLY the *heel*, in the *Mange*. A horse is said to *fly the heels*, when he obeys the spurs.

To *FLY* *grif*, in Falconry, is said of a hawk, when he flies at the great birds; as crane, geese, herons, &c.

FLY *on head*, is when the hawk, minding her quarry, takes her flight to the next check, as crows, &c. See HAWK.

FLY-bout, or *fight*, a large flat bottomed Dutch vessel, whose burthen is generally from four to six hundred tons. It is distinguished by a remarkably high stern, resembling a Gothic turret, and by very broad buttocks below.

FLY-*catcher*, *muscipa*, in Ornithology, the name of a genus of PASSERES in the Linnæan system, including twenty-one different species; the characters of which are, that the bill is almost triangular, bent inwards at its base, notched on both sides and beset with bristles, and that the nostrils are almost round. The birds of this genus found in Europe, are the *muscipa grisea* and *atriipilla*. The former, or spotted *fly-catcher*, has a large head, of a brownish hue, spotted with black; the back is of a mouse colour, the wings and tail dusky; the interior edges of the quill-feathers are edged with pale yellow; the breast and belly are white; the throat and sides under the wings are dulled with white; the bill is broad at the base, and ridged in the middle; the inside of the mouth is yellow; the legs and feet are short and black. This is a bird of passage, appears with us in the spring, breeds here, and retires in August. It builds its nest on the side of trees towards the middle, and, according to Morton, in his History of Northamptonshire, in the corners of walls, where spiders weave their webs. They feed on flies and cherries.

The other is called the *coal-d-*fly**, and is a rare species with us. It is a small bird of the *fructula* kind, and very nearly allied to the bee-eater, or peety-chaps. It is called also, in some places, *elven* and *jarin*. It is a little larger than the wren, and has a very sharp-pointed beak. Its head, neck, and back, are of a pale grey, and its throat and belly of a yellowish white. Its rump is white; its wings grey; its tail, feet, and legs, are brown; and its claws very slender. Ray's Ornithology, p. 158.

FLY-*tree*, in Natural History, a name given by the common people in America to a tree, whose leaves, they say, at a certain time of the year, produce *flies*. On examining these leaves about the middle of summer, the time at which the flies used to be produced, there are found on them a sort of bags of a tough matter, of about the size of a silken, and of a dusky greenish colour; on opening one of these bags with a knife, there is usually found a single full-grown *fly* of the grass-kind, and a number of small worms, which, in a day or two more, have wings, and fly away in the form of their parent.

The tree is of the mulberry-kind, and its leaves are usually very largely stocked with these insect bags, and the generality of them are found to contain the insects in the worm state; when they become winged, they soon make their way out. The bags begin to appear when the leaves are young, and afterwards grow with them; but they never rupture the leaf, or injure its shape. They are of the kind of leaf galls, and partake in all respects except size, of a species we have frequent on the large maple, or, as it is called, the sycamore. Philof. Trans. N° 431. See farther, Reaumur's Hist. vol. vi. p. 34. See PUCCION.

FLY-*worm*. See CATERPILLAR.

FLYERS, in Architecture, such stairs as go straight, and do not wind round, nor have the steps made tapering; but

but the fore and back-part of each tail, and the ends, respectively parallel to one another. So that if one flight do not carry you to your designed height, there is a broad half space, and then you fly again, with steps every-where of the same breadth and length as before.

FLYING, the progressive motion of a bird, or other winged animal, in the liquid air.

Flying is either *natural*, or *artificial*.

FLYING, natural, is that performed by an apparatus, or structure of parts, concerted for that end by nature herself. Such is that of most birds and insects, and of some fishes.

In Virginia and New-England they have monstrously large *fung* beetles. Philosoph. Transact. N^o 127. And in Languedo, grasshoppers about an inch long, where-with the ground, in several parts, in the year 1685, was covered one third of a foot deep. Ibid. N^o 182.

The parts of birds, &c. chiefly concerned in *flying*, are the wings and tail; by the first the bird sustains and wafts himself along; and by the second, he is assisted in ascending and descending, to keep his body poised and upright, and to obviate the vacillations thereof.

It is by the largeness and strength of the pectoral muscles, that birds are so well disposed for quick, strong, and continued *flying*. These muscles, which in men are scarce a sixteenth part of the muscles of the body, in birds exceed and outweigh all the other muscles taken together; upon which Mr. Willoughby makes this reflection, that if it be possible for man to fly, his wings must be so contrived and adapted, that he may make use of his legs, and not his arms in managing them.

The *flying* of birds is thus effected:

The bird first bends his legs, and springs with a violent leap from the ground; then opens, or expands the joints of his wings, so as to make a right line, perpendicular to the sides of his body; thus, as the wings, with the feathers therein, constitute one continued lamina, being now raised a little, and vibrating the wings, with great force and velocity, perpendicularly against the air, the air, though a fluid, resists those succussions, both from its natural elasticity, and from its elasticity, which makes it restore itself after it has been compressed, and re-act as much as it has been acted on: by such means is the whole body of the bird protruded. The facility of nature is very remarkable in the opening and recovering of the wing for fresh strokes. To do it directly, and perpendicularly, it must needs have a great resistance to overcome; to avoid which, the bony part, or bend, of the wing, into which the feathers are inserted, moves sideways, with its sharp end foremost, the feathers following it like a flag.

The resistance the air makes to the withdrawing of the wings, and consequently, the progress of the bird will be so much the greater, as the wail, or stroke, of the fin of the wing is the longer; but as the force of the wing is continually diminished by this resistance, when the two forces come to be in equilibrium, the bird will remain suspended in the same place; for the bird only ascends so long as the arch of air, the wing describes, makes a resistance equal to the excess of the specific gravity of the bird above the air: if the air, therefore, be so rare as to give way with the same velocity as it is struck withal, there will be no resistance, and, consequently, the bird can never mount.

Mr. Ray, Willoughby, &c. have supposed the tail to do the office of a rudder, in steering and turning that body this way, or that; but Borelli has shown it to be unfit for any such office. The *flying* of a bird, in effect, is quite a different motion from the sailing of a ship: birds do not vibrate their wings toward the tail, as ours are thrust towards the stern, but wait them downwards; nor does the tail of the bird cut the air at right angles, as the rudder does the water, but is disposed horizontally, and preserves the same situation, what way soever the bird turns.

In effect, as a vessel in the water is turned about on its centre of gravity to the right, by a brisk application of the oars to the left, so a bird, in beating the air with its right wing alone, towards its tail, its fore-part will be turned to the left; as when in swimming, by only striking out with the right arm and leg, we are driven to the left.

Add, that birds with long necks have another way of altering their course; for, by only inclining the head and neck towards this or that side, the centre of gravity of the whole being changed, the bird will proceed according to this new direction.

Birds never fly upwards in a perpendicular line, but always in a parabola, the line described by projectiles. In a direct ascent, the natural and artificial tendency would oppose and destroy each other, so that the pro-

Vol. II. N^o 136.

gress would be very slow. In a direct descent, they would aid one another, so that the fall would be too precipitate. Indeed the hawk, we frequently find, takes that advantage in seizing of the partridge: but ordinarily birds keep their wings expanded, and at rest, to retard their descent: and at the same time stretch out their legs.

FLYING, artificial, is that attempted by men by the assistance of mechanics.

The art of *flying* is one of the great desiderata of mechanics: it has been attempted in divers ages; the discovery of it might prove of great service, and also of great disservice to mankind.

No body seems to have had so fair for that invention, as our famous friar Bacon, who lived upwards of five hundred years ago. He not only affirms the art feasible, but assures us he himself knew how to make an engine, in which a man sitting might be able to carry himself through the air like a bird; and affirms that there was another person who had actually tried it with success. The secret consisted in a couple of large thin hollow copper globes, exhausted of air, which being much lighter than air, would sustain a chair, whereon a person might sit.

F. Francisco Lanza, in his *Prothema*, proposes the same thing, as his own thought. He computes that a round vessel of plate-brass, fourteen feet in diameter, weighing three ounces the square foot, will only weigh 1818 ounces; whereas a quantity of air of the same bulk will weigh 215 1/2 ounces; so that the globe will not only be sustained in the air, but will carry with it a weight of 573 1/2 ounces: and by increasing the bulk of the globe, without increasing the thickness of the metal, he adds, a vessel might be made to carry a much greater weight.

But the fallacy is obvious; a globe of the dimensions he describes, Dr. Hook shows, would not sustain the pressure of the air, but would be crushed inwards. Therefore, in whatever ratio the bulk of the globe were increased, in the same must the thickness of the metal be also, and consequently the weight increased: so that there would be no advantage in such augmentation.

The same author describes an engine for *flying*, invented by the sieur Bismier, a smith of Sable, in the county of Maine. Vide Philosoph. Collect. N^o 1.

The famous bishop Wilkins was so confident of success in this art, that he seems to intimate, that, in future ages, it will be as usual to hear a man call for his wings when he is going a journey, as it is now to call for his boots. See Math. Magic, &c. ch. 7. Discovery of a new World, prob. xiv. p. 135. Secret and Swift Messenger, ch. iv.

FLYING army and camp. See CAMP.

FLYING of colours, is used by painters to denote their want of dexterity, which they express by their *slangings*.

FLYING-fish, a name given by the English writers to several species of fish, which by means of their long fins have a method of keeping themselves out of water for some time. The *flying-fish*, most properly so called, is the *exocoetus*, of the ancient authors, and of Artedi. See Tab. IV. of Fish, N^o 41.

It is called also the *astronotus*, *larunda*, and *magi-alatus*, or winged mullet, by authors; but they use these words indifferently for this and the other kind.

Its general size is about six inches in length; its head is covered with scales, and it resembles the berring in the form of its body, but the back is flat. The scales are large and silvery; the dorsal fin is small; its eyes are large; the mouth is small, and is placed low in the head; and its jaws are granulated, rather than toothed. Its belly is white; its tail forked; its gills fins, commonly called its wings, are so long, as when laid close to the body to reach the tail, and they are in fact double; a small fin composed of a series of short nerves or rays, connected by a small membrane standing before each. These wings are of an olive colour on their upper side, and are spotted with very beautiful blue spots near their edges.

This fish, when it pleases, is able to rise out of the water, and fly to a considerable distance in the air; but when its wings are dry, it is obliged to plunge again into the water to moisten them. It does this often, when pursued by an enemy; and whole shoals have been seen thus flying together. It is common in the Mediterranean, and some other seas, but is seldom known in ours, nor in any of the colder climates. See a minute and accurate description of the *exocoetus volitans*, or *flying-fish*, in the Phil. Trans. vol. lxxvii. part ii. p. 791.

FLYING-fish is also the name of a fish of the gurnard kind. See *Sapphirine Gurnard*.

FLYING pinion, is a part of a clock having a fly or fan, whereby to gather air, and so bridle the rapidity of the clock's motion, when the weight descends in the striking part. See CLOCK.

FOAL, or *colt*, the young of the horse kind. The word colt, simply spoken, is, among the dealers, understood to mean the male kind, the female, or mare colt, being called a filly.

Colts are usually foaled in the beginning of summer, and it is the custom to let them run with the mare till Michaelmas, when they are to be weaned. This is to be done sooner or later, according as the cold weather comes in. Some of them are for not having them weaned till the middle of November, and that three days before the full of the moon, if it happen near that time. And some of the best writers on this subject are of opinion, that we do not let the foal suck long enough, and that this is the reason why they are so very young before they are fit for use. These authors are of opinion, that a colt ought always to suck the whole winter, and that this would make them fit for service a great deal sooner than they are at present.

When first weaned, they must be kept in a convenient stable, with a low rack and manger for hay and oats, that they may eat freely and easily, and the hay must be very sweet and fine, especially at first; a little wheat bran should be mixed with the oats, in order to keep their bodies open, and make them eat freely and drink freely. It has been observed, that the eating too much oats has rendered colts blind; but the cause has been wrongly ascribed to the heating quality of the oats. If the oats are bruised in a mill before they are given them, though they eat more of them, they never happen any mischief of this kind; but endeavouring with their teeth to break and chew them when whole, they are apt to breach and swell the vessels of the head, and occasion a fulness of blood about the eyes, which often terminates in inflammation, and in blindness.

The difficulty of chewing oats, and not their heating nature, is therefore the true cause of this mischief; and if this be obviated by first bruising the grain, the colt always grows the better for eating it. His legs do not grow thick, but he becomes broader and better knit, and as he grows up, will bear fatigue much better than if he had been fed only with bran and hay. Above all things, these creatures are to be kept from wet and cold, while they are young, for nothing is more tender than a colt, and the mischief he gets at this time are not so easily overcome. Experience shows the great advantage of housing and taking care of colts: for if the same stallion cover two mares, both alike in age, beauty, and all other particulars, and these bring both foals of the same sex, so that there is no room to expect the least difference between them; let one of these colts be housed every winter, and let the other always run abroad, it will be found as they grow up, that the colt which has been kept abroad, shall have large fleshy shoulders, bony and gony legs, weak pasterns, and bad hoofs, and shall be a dull heavy creature; and that the other, which has been housed and taken care of, shall have a fine forehead, be well shaped, have good legs and good hoofs, and be of good strength and spirit.

From this it may be learned, that it is of no consequence to have a good stallion, and a good mare, if the colts are frosted in the breeding year. It is observed, that some colts, under the age of six months, though the mare yields plenty of good milk, yet decay and waste daily. They are, in this case, always troubled with a cough. The breeders have a great many fantastical remedies in such cases, as the bag wherein the creature was foaled, the lungs of a fox, and the like; but a little liquorice and elecampane powder mixed with honey and milk, is a remedy greatly to be preferred to all these.

When the colts are kept up in the winter, they are not to be continually immured in the stable, but in the middle of the day, when the sun shines warm, they should always be let out to play about an hour or two; and when the winter is spent, they should be turned into some dry ground, where the grass is sweet and short, and where there is good water, that they may drink at pleasure. The winter after this, they may be kept in the stable without any further care than that which is taken of other horses; but after the first year, the mare colts and horse colts are not to be kept together.

This may be the method every summer and winter till they are broke for use, which may be when they are three years old; and they will take the breaking much more easily, after this sort of breeding, than if they had been all the time running about wild. For ordering them the second year as the other horses are ordered, they will be tame and gentle like them, and will not flounce and plunge about on the full mounting, as they otherwise would, but will take the saddle quietly. The common way of breaking a colt, by beating him and tiring him by running over plowed fields, however necessary it may be in a colt that has always run wild, is not to be chosen when it can be avoided; for it is breaking and spoiling the creature's spirit. Using him to other horses, and

winning him by gentleness, is a vastly preferable way. It is proper to wear no spurs for some time with a newly broken horse.

In order to make him endure the saddle well, the way is to make it familiar to him, by clapping it with the hands as it lies on his back; then swaying upon it, and dangling the stirrups by his sides, rubbing his sides with them, and bringing him thus to be used to every thing about him. Then the crupper should be often strained, the girths loosened and tightened, and the stirrups taken up and let down at times, all the while making much of him. This will make every thing easy to him, and will make him gentle without breaking his spirit.

As soon as he will not wish the saddle obediently, the mounting of him is to be considered. In order to this, put a trench of a full mouth into his mouth, and throw the reins over the fore part of the saddle, so that he may have full feeling of it; then put on a martingale, buckled at such a length, that he may justly feel it when he jerks up his head; a broad piece of leather is then to be put up his neck, and the ends made fast by plaiting it, or some other way at the withers, or before the wind-pipe, about two handbills below the thropple, betwixt the leather and his neck; let the martingale pass so that, at any time when he offers to duck or throw down his head, the cavalcade being placed upon the tender gristle of his neck, may correct and punish him. This will make him bring his head to, and turn him to the rein. See **HORSE**.

FOGAGE, or **FORAGE**, fire-money, hearth-money, or chimney-money. See **FRAGO**.

FOCILE, **FOCIL**, in *Anatomy*, a name the Arabs give to the two bones of the arm, reaching from the elbow to the wrist.

The biggest, which is what we call the *radius*, and *ulna*, they call the *greater foel*, *foel major*.

The less, which we call *radius*, they call the *foel minor*.

The like is observed with regard to the bones of the leg. The biggest of which, by the Latins called *tibia*, the Arab writers, &c. call the *great foel*; and the less, or *fibula*, the *less foel*.

FOCUS, in *Geometry*, and the *Conic Section*, is applied to certain points of the *parabola*, *ellipse*, and *hyperbola*; wherein the rays reflected from all parts of these curves do concur or meet.

The **FOCUS** of an **ELLIPSE** are two points, as **F**, **T**, **Tab. Con. Fig. 21**, in the axis **AB**, on which, as centre, the figure is described: or, two points in the longer axis, whence two right lines being drawn to any point in the circumference, shall be together equal to the axis itself. These are also called *anallaxes*. See **CONIC SECTION**.

To find the *foi* of an *ellipse*. See **ELLIPSE**.

FOCUS of the *hyperbola*. See **CONIC SECTION**, and **HYPERBOLA**.

The **FOCUS** of a *parabola* is a point in its axis, as **F** (**Tab. Conic. fig. 18**.) wherein the semiordinate **PN** is equal to the semi-parameter; or, a point in the axis distant from the vertex, by a fourth part of the parameter, or *latus rectum*.

It is demonstrated in *conics*, 1. That in a parabola, the distance of the *focus* from the vertex, **AF**, is to the parameter in a subquadruple ratio.

2. That the square of the semiordinate is quadruple of the rectangle of the distance of the *focus* from the vertex, and the abscissa.

3. That the right line **FM**, *fig. 19*, drawn from the *focus F* to the extremity of the semiordinate of the parabola, is equal to the aggregate of the abscissa **AP**, and the distance of the *focus* from the vertex **AF**. See **CONIC SECTION**.

FOCUS, in *Optics*, is a point wherein several rays concur, and are collected; either after having undergone refraction, or reflection.

It is thus called, because the rays being here brought together, and united; their force and effect are increased; so that they become able to burn: accordingly, it is in this point, that bodies are placed to sustain the force of burning glasses, or mirrors.

It must be observed, that the *focus* is not, strictly speaking, a point; the rays are not all accurately collected into the same place: Hergens demonstrates, that the *focus* of a lens convex on both sides, is of the thickness of the lens.

FOCUS, in *Diptics*, is the point wherein refracted rays, rendered convergent by refraction, do concur, or meet, and cross the axis.

The same point is also called the *point of concursus*, or *convergence*.

FOCUS, *Foveol*, in *Diptics*, is the point from which refracted rays, when by refraction they are rendered divergent, do begin to diverge, or recede from each other.

The same point is also called *passum diffusum*, or *point of*

of *divergency*, in opposition to the *focus* which is called the point of concurrence. Suppose, e. g. the concavity of a glass to be *abc*, Tab. II. *Optics*, fig. 21. and its axis *de*; let *fg* be a ray of light falling on the glass parallel to the axis *de*, and let *b* be the centre of the arc *abc*. This ray *fg*, after it has passed the glass, at its emergence at *e*, will not proceed directly to *b*, but will be refracted from the perpendicular *de* and become the ray *g*. Draw then directly *g* to *b*, so that it may cross the axis in *e*. The point *e* is found, is called by Mr. Moynaux the virtual *focus* or point of divergency.

The effect of convex glasses, or lenses, is to render the rays, transmitted through them, convergent, and to bring them together into a *focus*, which will be nearer or farther off, as the lens is a portion of a greater or less sphere.

The effect of concave lenses is, to render the rays transmitted through them, divergent, or to disperse them from a virtual *focus*.

For the place, position, distance, &c. of the *focus* of rays refracted through plano, convex, and concave mediums of divers densities, as air, water, glass, &c. see REFRACTION, LENSES, &c.

The laws of the *focus* of glasses, and the methods of finding the same, being those of small use and importance, we shall here submit them apart, as delivered and corroborated by Mr. Moynaux, in his *Dioptrica Nova*.

1. The *focus* of a convex glass, i. e. the point wherein parallel rays transmitted through a convex glass, whose surface is the segment of a sphere, do unite, is distant from the pole or vertex of the glass, almost a diameter and half of the convexity.

2. In a plano-convex glass, the *focus* of parallel rays, or the place where they unite with the axis, is distant from the pole of the glass a diameter of the convexity, provided the segment do not exceed thirty degrees.

The rule or canon in plano-convex glasses is as 167 : 193 :: *fo* is the radius of the convexity : to the refracted ray taken to its concavity with the axis ; which in glasses of larger spheres is almost equal to the distance of the *focus* taken in the axis.

3. In double-convex glasses of the same sphere, the *focus* is distant from the pole of the glass about the radius of the convexity, if the segment be but thirty degrees.

But if the concavities be unequal, or if the two sides be segments of different spheres, then the rule is,

As the sum of the radii of both convexities : to the radius of either convexity alone : so is the double radius of the other convexity : to the distance of the *focus*.

Here observe, that the rays which fall nearer the axis of any glass, are not united with it so near the pole of the glass as those farther off : nor will the *focus* distance be so great in a plano-convex glass, when the convex side is towards the object, as when the plain side is towards it.

Hence it is truly concluded, that, in viewing any object by a plano-convex glass, the convex side should always be turned outward : as also in burning by such a glass.

FOCUS, for the virtual, observe, 1. That in concave glasses, when a ray falls from air parallel to the axis, the virtual *focus*, by its first refraction, becomes at the distance of a diameter and a half of the concavity.

2. In plano-concave glasses, when the rays fall parallel to the axis, the virtual *focus* is distant from the glass the diameter of the concavity.

3. In plano-concave glasses, as 107 : 193 :: *fo* is the radius of the concavity : to the distance of the virtual *focus*.

4. In double concave of the same sphere, the virtual *focus* of parallel rays is at the distance of the radius of the concavity.

But, whether the concavities be equal or unequal, the virtual *focus*, or point of divergency of the parallel rays, is determined by this rule :

As the sum of the radii of both concavities : is to the radius of either concavity : so is the double radius of the other concavity : to the distance of the virtual *focus*.

5. In concave glasses, exposed to converging rays, the point to which the incident ray converges, be distant from the glass farther than the virtual *focus* of parallel rays, the rule for finding the virtual *focus* of this ray is this :

As the difference between the distance of this point from the glass, and the distance of the virtual *focus* from the glass : is to the distance of the virtual *focus* : so is the distance of this point of convergence from the glass : to the distance of the virtual *focus* of this converging ray.

6. In concave glasses, if the point to which the incident ray converges, be nearer to the glass than the virtual *focus* of parallel rays, the rule to find where it crosses the axis, is this :

As the excess of the virtual *focus*, more than this point of convergency : is to the virtual *focus* : so the distance

of this point of convergency from the glass : is to the distance of the point where this ray crosses the axis.

Rule for finding the Focus of glasses.—To find the *focus* of a convex spherical glass, being of a small sphere, apply it to the end of a scale of inches, and decimal parts, and expose it before the sun ; upon the scale you will have the bright intersection of the rays measured out : or, expose it in the hole of a dark chamber, and where a white paper receives the distinct representation of distinct objects, there is the *focus* of the glass.

For a glass of a pretty long *focus*, observe some distant object through it, and recede from the glass till the eye perceives all in confusion, if the object begun to appear inverted ; here the eye is in the *focus*.

For a plano-convex glass : make it reflect the sun against a wall ; you will on the wall perceive two sorts of light ; one more bright within, another more obscure : withdraw the glass from the wall, till the bright image is in its least dimensions ; the glass is then distant from the wall about a fourth part of its *focus* length.

For a double convex : expose each side to the sun in like manner, and observe both the distances of the glass from the wall. The first distance is about half the radius of the convexity turned from the sun ; and the second, about half the radius of the other convexity.

Thus we have the radii of the two convexities ; whence the *focus* is found by this rule :

As the sum of the radii of both convexities : is to the radius of either convexity : so is the double radius of the other convexity : to the distance of the *focus*.

FOCUS, in Catoptrics, is a point wherein the rays reflected from the surface of a mirror, or speculum, and by reflection rendered convergent, do concur, or meet.

The effect of concave mirrors is to collect the rays falling on the concave surface into a *focus*.

The effect of convex mirrors is to disperse the rays falling on them, or render them more divergent.

For the laws of the *focus* of rays reflected from mirrors, or specula, see MIRRORS.

The *focus* of concave glasses are had by reflection : for, as a concave mirror burns at the distance of about half the radius of the concavity ; so a concave glass being supplied with a reflecting speculum, unites the rays of the sun at the distance of about half the radius of the concavity.

For the Focus of all glass generically.—Dr. Halley furnishes us with a general method for finding the *focus* of spherical glasses of all kinds, both convex and concave : exposed to any kinds of rays, either parallel, converging, or diverging ; under the following problem.

To find the *focus* of any parcel of rays diverging from, or converging to, a given point in the axis of a spherical lens, and inclined thereto under the same angle, the ratio of the lines of refraction being given :

Suppose G L, (Tab. *Optics*, fig. 20.) a lens ; P a point in its surface : V its pole, C the centre of the sphere whereof it is a segment : O the object, or point in the axis, to or from which the rays do proceed ; and OP a given ray ; and suppose the ratio of refraction to be as *r* to *i*. Then making CR to CO, as *i* to *r* for the immersion of a ray ; or as *r* to *i* for the emergence (i. e. as the sines of the angles in the medium which the ray enters, to the corresponding lines in the medium out of which it comes), and laying CR, from C towards O, the point R will be the same for all the rays of the point O. Lastly, drawing the radius PC, if need be, continued ; with the centre R, and distance OP, describe a piece of an arch, intersecting PC in Q. The line OR, being drawn, shall be parallel to the reflected ray ; and PF, being made parallel thereto, shall intersect the axis in the point F, the *focus* sought.

Or, make it, as CQ : CP :: CR : CF, then will CF be the distance of the *focus* from the centre of the sphere.

This author gives a demonstration of the method, and adds various figures, exhibiting the various cases of rays either diverging or converging as they enter, or emerge out of, the surface either of a convex or concave lens.

From this principle all the rules for the *focus* of rays parallel to the axis, as likewise for the principal *focus* where the rays nearest the axis do unite, are deduced.

Hence, 1. If OP be equal to CR, the points Q and C are coincident, and the ray OP, after refraction, run on parallel to the axis. 2. If the point Q fall on the same side of the axis, as is the point P, then the beams after refraction do tend on, either diverging or converging, as before ; but if Q fall on the other side of the axis, the diverging rays are made to converge by a convex, or the converging to diverge by a concave glass. 3. If OP do exceed CR, the *focus* is in all cases on the same side of the glass, as is the centre of the sphere C. But contrariwise, if OP be less than CR, the *focus* falls on the other side of the glass beyond the vertex V. 4. An object may be so placed, that the rays next the axis of a convex glass shall

shall have an imaginary focus transmitting diverging rays, when the more remote parts thereof shall make them converge to a real focus. 5. If OV, the distance of the object from the pole or vertex of the glass, be taken instead of O P, then will C Q be the difference of OV and C R; and as that difference is to C R, so is the radius C V to C F, the distance of the principal focus from the centre of the sphere, where the glass is a segment. Or else, as C Q : O P :: R Q : P C :: V F, the focal distance from the pole of the glass. Whence follows a general rule for the use of all glasses: only according to Corol. 3. in O V do exceed C R, the focus is on the same side of the glass as the centre of the sphere: but if C R be greater, then the focus is on the opposite side of the glass, whence it will be determined whether the focus be real or imaginary.

What has been said of one surface of the lens, is easily applicable to the other, taking F the focus for an object.

PODDER, any kind of meat for horses, or other cattle: in some places hay and straw mingled together are more peculiarly denominated *podder*.

In the civil law it is used for a prerogative that the prince has, to be provided of corn, and other meat, for his horses, by the subjects, in his warlike expeditions.

PODDER, in Mining, is a measure containing twenty-two hundred and a half weight, though in London but twenty hundred weight.

PODINA, a name some authors give to the Labyrinth in the bone of the ear.

PŒCES. See **PACES**.

PŒCIALES. See **PŒCIALES**.

PŒCULA. See **FECULA**.

PŒCUNDITY. See **FECUNDITY**.

PŒNICULUM. See **FENNEL**.

PŒNUM *Græcum*. See **PENUGREEK**.

PŒNUM *sanctum*. See **SANCT**.

PŒTOR, in Medicine, sinking or feid *EFFLUVIA*, proceeding from the body, or the parts thereof.

Fætor arise from stagnant, extravasated, corrupted, or poisoned humours: as also from any thing capable of attenuating and volatilizing the oils and salts, as subtilness, heat, too much motion, acrimony of food, &c.

PŒTORIARIUM, trench of the nobility: a sort of disease arising from a deep ulcer within the nose, yielding a foetid smell.

Its cause, according to Galen, is a sharp humour falling from the brain upon the maxillary processes.

This is one of the causes for which marriage might be formerly annulled.

PŒTORIUM, a term used by medical writers to express that ill smell in the mouth, after, though often, improperly, called by an sinking breath. This is a malady arising in different cases from very different causes; as from the scurvy, and particularly that species of it which affects the mouth, and is therefore called *stomatitis* from the French *pox*: from an ulceration whether simple or fistulous in the lungs, which is the case in consumptions; from ulcers in the mouth; from caries or rotteness of the teeth, or from any other impurity of them; from crudities in the stomach arising from a bad digestion, and in particular, from a weakness about the left orifice of the stomach, from which part the foetid vapours will often arise in very great abundance.

Method of cure. According to the different causes of this disorder, it requires a very different method of cure. In cases where it depends on the scurvy, pox, or other diseases, those diseases are to be attacked by the proper medicines, in order to its cure; when it arises from a carious tooth, there is no cure for it, but drawing the tooth; when the impurities of the teeth occasion it, the cleaning them proves a cure. Juncker's *Consp. Med.* p. 607.

FŒTUS, in Anatomy, denotes the child, while yet contained in the mother's womb; but particularly after it is perfectly formed: till which time it is more properly called **EMBRYO**.

The manner of the conception, or generation of the *fætus*, is matter of great controversy. That all the parts of the animal did exist, and that its fluids were in motion, before generation, is generally allowed; but whether the animalcule was lodged in the male, or female, has been much disputed. See **GENERATION**, **CONCEPTION**, and **PREGNANCY**.

The first thing that appears of a *fætus*, is the placenta, like a little cloud, on one side of the external coat of the egg: about the same time the spine is grown big enough to be visible; and a little after the cerebrum and cerebellum appear like two small bladders; next, the eyes stand prominent in the head: then the ponsilium saliens, or pulsation of the heart is plainly seen. The extremities discover themselves last of all.

The formation of the bones in a *fætus* is very gradual and regularly performed. In the first two months there is nothing of a bony nature in the whole; after this, the hardness of the parts where the principal bones are to be situated becomes by degrees perceptible. Dr. Keeling describes the progress of the ossification from scleotons which he had prepared from *fætusi* of two months, and thence up to nine. In the first two months, or till the end of that time, there appears not any thing bony; after this in the third and fourth months, and so on, the several parts, one after another, acquire their bony nature. In the first stages every thing is membranous, where the bones are to be; these by degrees transmute into cartilages; and from these by the same sort of change continued, the bones themselves are by degrees formed. All this is done by nature, by such flow, though such certain progressions, that the meek eye can never see it doing, though it easily sees it when done.

While *fætusi* continue in the womb, their muscles commonly act only by their natural contraction, or the *fætus* is said to be in a sleeping state; but sometimes, when its ease or preservation requires a change of situation, it seems to perform some voluntary motions, which are called its *stirrings*. The posture of the child in the womb, is owing to the muscles being left to their natural contractions, the stronger always prevailing, till their antagonists exert such a resistance by being stretched, as brings them to an equilibrium.

Fætusi increase proportionally less, the longer they continue in the womb. Mairacau pretends, that the increase of a child, is sixty-four times its own weight in triple the time. Thus he says, that at the birth, a child weighs twelve pounds, or sixteen ounces each; at the three months, it weighs three ounces; at one month 3 of a drachm; and at ten days less than half a grain. Monro in *Med. Ess. Edinb.* vol. II. p. 142.

FŒTUS, in the womb, *formation of the*. The *fætus*, when formed, is almost of an oval figure, while it lies in the womb: for its head hangs down, with its chin upon the breast: its back is round; with its arms it embraces its knees, which are drawn up to its belly, and its heels are close to its buttocks; its head upwards, and its face towards its mother's belly. About the ninth month, its head, which was hitherto specifically lighter than any other part, becomes specifically heavier, its bulk bearing a much smaller proportion to its substance than it did.

The consequence of this change is, that it tumbles in the liquor which contains it; its head falls down, its feet get up, and its face turns towards its mother's back. But being now in an irksome posture, though, at the same time, a favourable one for its exit, the motion it makes for its relief gives frequent pains to the mother, which cause a contraction of the womb for the expulsion of the *fætus*.

What some anatomists pretend to allege farther, as to the posture of the *fætus* in the womb, in the several stages of gestation, is very precarious.

In the first month it is of no moment how it lies in the womb: in the latter months, after the *fætus* is grown not only quick, but robust, it frequently changes its posture of itself, as not only the mothers themselves feel, but any other person, by laying the hand on their bellies, frequently may. However, its ordinary posture is supposed to be sitting: as the time of birth draws near, it turns itself, and presents the head to the os uteri; though sometimes it offers the feet first, and sometimes lies across, and offers either a hand, a knee, or the like: these are irregular situations, and without considerable address of the midwife in turning the *fætus*, both the mother and the infant are in danger. See **DELIVERY**.

FŒTUS, *anatomy of the*. The *fætus* is inclosed in two membranes, or coats; the inner, which immediately invests the *fætus*, and the liquor wherein it lies, is called the **AMNION**; the outward membrane is called the **CHORION**.

In some animals there is a third membrane, called the **ALLANTOIS**, whose place is between the other two, and which serves for the discharge of the urine of the *fætus*, brought hither by the *urachus*.

Dr. Needham seems to have discovered something analogous herein in the human *fætus*, and calls it the *membrana urinaria*; but others chuse only to make it a duplicate of the chorion; though the necessity of such third membrane be the same in men, as in cows, sheep, &c.

There are some differences in the structure, mechanism, and proportion of the parts of a *fætus*, from those of an adult; and even some additional and extraordinary parts, by which the nutrition of this zoophyte, or plant-animal, as it is called, and the circulation of the blood therein, are effected.

The principal variations are about the liver, heart, and lungs.

Of these, the most considerable are the umbilical vessels, which are two arteries, a vein, and the urachus, arising from the placenta, and conveyed through the navel to the liver of the *fœtus*, near the navel all which, after the birth, drying up, become impervious and useless.

In the liver itself there is an extraordinary communication between the porta and cava, called *cavali venosus*, which, after the birth, gradually dries up. In the heart, at the mouth of the vena cava, is the foramen ovale, whereby that vein has a communication with the pulmonary vein: there is also a communication between the aorta and pulmonary artery, by means of the canal's arteriosus, which passes between the two, at about two inches distance from the base of the heart. It is by means of these two canals or passages, that the blood has been supposed to circulate in the *fœtus* while inclosed in the womb; they serving to convey and pass the blood from the heart into the arteries, and from the veins into the heart again, without its passing through the lungs, which are now useless.

The lungs of a *fœtus* are of a darker colour, and closer consistence, than after they have been breathed into, as appears from their swimming in water after birth, which they will not do before; which difference has been said to afford an useful experiment, in case of the suspected murder of children: for if they were still-born, the lungs sink in water; if born alive, they swim. But this notion is not well founded; because the uninfused lungs become specifically lighter than water as soon as any degree of putrefaction takes place in them, and this happens soon after the death of the child; besides, where the utmost care has been taken to preserve the child, it has breathed once or twice, and then died.

The two canals above mentioned serve only to prevent the obstruction the blood would otherwise have within the lungs, before they have been opened. After respiration has opened the lungs, the blood taking its course through them, those passages close up.

The head of the *fœtus* is much bigger in proportion to the body than afterwards; the bones and brains are softer, the sutures open, and they leave a great space on the top of the head, covered only with a membrane; and the glands, particularly the thymus and renals, are bigger and softer. From other differences in the proportion, see EMBRYO.

FOETUS, nutrition of the. How the nutrition of the *fœtus* is performed, is disputed among the learned. Heister is of opinion, that the nutrition of the *fœtus*, during the first months, while the organs of concoction are not yet formed, is probably effected by means of the navel-string alone. But in the more advanced state of the *fœtus*, in the latter months, he supposes, that it is also nourished by the mouth, by means of a soft and somewhat gelatinous fluid that surrounds it, and which is probably secreted from the amnios: in support of which opinion he observes, 1. That a fluid similar to that of the amnios is found in the mouth, the œsophagus, and the stomach, not only of the human *fœtus*, but in that of quadrupeds. 2. That this fluid is also found in the small guts of the *fœtus*, but altered and digested. 3. That there are also found in the larger intestines real faeces, called meconium: sometimes the whole flum is full of these. 4. That in the first months there is a great quantity of this fluid surrounding the *fœtus*; but in the latter months, there is little of it, and the consumption of it is not easily accounted for in any other way than by its being swallowed by the *fœtus*. 5. That the liquid itself is so extremely proper for the nutrition of the *fœtus*, that a more fit one could not be formed or desired. 6. That it seems to be continually pressed into the mouth, œsophagus, and stomach of the *fœtus*, by the perpetual rectitude of the uterus itself, and by the pressure of the muscles of the abdomen, and of the ambient air.

Hippocrates, among the ancients, was of opinion, that the *fœtus* was nourished both by the mouth, and by the umbilical vessels. He maintains, that the child in the womb, with its lips compressed together, sucks nourishment; for which he assigns this reason, that unless the child had sucked in utero, it neither could deposit excrement, nor know how to suck so soon as it is born. The celebrated Harvey maintained this doctrine; only that he substituted an albuginous aliment in place of Hippocrates's menstrual blood. Mr. Gibson, in the Medical Essays of Edinburgh, vol. i. p. 120. has also adopted this opinion, that the *fœtus* is nourished by the mouth and by the navel also, as most probable.

He alleges, that the fluid contained in the amnios, and in which the *fœtus* swims, is not an excrementitious liquor, but a *nutritiva*; so that it is found in very considerable quantities, before the parts of the *fœtus* are visibly delineated; and nature hath provided the delicate membrane, called the allantois, principally for pre-

venting the urine of the *fœtus* from mixing with the liquor amni, its food. Further, the mouth, may even its chafin, long before the lips are observable, is always open; for air blown up it through a pipe will evidently separate its sides; and Heister remarks to this purpose, that he has more than once, in the cold winter season, found the liquor amni frozen, and continued through the mouth and œsophagus to the stomach in a pretty large column. Mr. Gibson adds, that there have been examples of human *fœtus*, which have been brought into the world alive, either altogether wanting the umbilicus and its vessels, or, at least, having the umbilical rope broke asunder. He then subjoins two analogical arguments in confirmation of this opinion, concerning the nutrition of the *fœtus* by the mouth and the umbilical vessels, viz. one, deduced from the vegetation of plants, which, he says, in female have two roots, the femoral, whose fibres are inserted into the cotyledones of the seed; and the plantal, which succeds the former, and supersedes the use of the cotyledones, which die and fall off: and the other, from the apparatus for nourishing the chick in ovo; the albumen on answering the same purpose, with regard to the chick, as the liquor amni does with respect to the *fœtus* in animals.

Dr. Fleming has lately produced a fact in support of this hypothesis, viz. that he had found hairs in the meconium of the *fœtus* of a calf: these, he apprehends, were loosened from the skin, and afterwards floating in the liquor amni, were propelled with it into the stomach and intestines by the alimentary passage. But from a single fact no general conclusion can be satisfactorily deduced. He adds, as a proof of the alimentary nature of the liquor amni, that it is concretible by heat, like the yolk of an egg. Phil. Trans. vol. xlix. art. 42.

Dr. Monro, on the contrary, is of opinion that the *fœtus* in viviparous animals is nourished by the navel alone. He has given a curious dissertation on this subject in the Medical Essays, vol. ii. p. 102, &c. where he observes, 1. That the *fœtus* is capable of receiving its whole nourishment by the umbilical vein alone, whereas no *fœtus* can subsist without the umbilical vessels. 2. That the liquor of the amnios is ill calculated, in its natural state, for the food of a *fœtus*; and becomes altogether unfit food in morbid cases. 3. That it is highly improbable that a creature should furnish its subsistence out of its own body, which must be the case, if the *fœtus* feeds on the liquor of the amnios. 4. That it cannot be inferred from any resemblance of the liquor of the stomach and amnios, nor from any other appearances, that the liquor of the amnios is ever sent down into the stomach. 5. That no direct proof can be had of the liquor of the amnios being pressed or swallowed down a bit, on the contrary, all circumstances make it probable, that it does not go down. 6. That all the phenomena of a *fœtus* can most reasonably be accounted for, without supposing the liquor of the amnios to be any part of its food; hence he thinks it reasonable to exclude the mouth from the office of conveying the aliment of the *fœtus* of viviparous animals, and to believe that all their nourishment is conveyed by the umbilical vessels.

Dr. Monro has also given us several curious observations relating to the question about the nutrition of the *fœtus* of oviparous animals.

He has also there considered the nourishment of plants in a *fœtus* state. And he shews the analogy there is between these and animal *fœtus*. To fix the analogy between animals and plants, he observes, that the former may be said to remain in the state of a *fœtus*, so long as the young creature is solely nourished by liquors furnished by the uterus of the parent; and plants are to be considered as *fœtus* only, while the seed is ripening, and before the earth, water, moisture of the air, &c. have communicated immediately any matter for its increase.

The same author has given us some practical corollaries, from his essay on the nutrition of *fœtus* of viviparous animals, where he makes several very just observations relating to abortion, its causes, and the method of preventing it in many cases.

The liquors sent into the *fœtus* by the umbilical vein, not having their propelling force communicated from the mother, the state of the mother's pulse cannot affect the child otherwise than by occasioning abortion, or vitiating the fluids. Hence the impressions said to be made on children by the imagination of their mother, cannot be accounted for physically. Hence also children may be infected with the diseased juices of the mother; but it is possible for them to escape catching their mother's diseases, if either these be only topical, without affecting the whole mass of the fluids; or even when the mother's blood is spoiled, the child may be free of her disease. If the morbid particles be such, so the placental vessels cannot absorb.

The mother supplies liquor to the *fetus*, which returns to her by means of the ducts and umbilical vein. This is proved from observations, *fœtus* whose placenta were not in the least separated from the mother, having been quite exhausted of blood by the mother's stage of a hemorrhage; and Dr. Moore acquiesces in that he has seen children pale and weak by violent bleeding in the time of labour.

The liquor is not carried from the mother to the *fetus* or from the *fetus* to the mother by continued canals. This is, the uterine arteries and veins do not anastomose with the veins and arteries of the secundines; but the extraneous of the umbilical vein take up the liquor by absorption, in the same way as the lacteal vessels do in the paps; and the umbilical arteries pour their liquor into the large cavity of the funis, or other cavities analogous to these.

It is a question, whence the *fetus* has its red blood. Dr. Mead answers, that *fœtus* in viviparous animals have their red blood from the same source that chickens in ovo have theirs; which can be no other than the action of their heart, and of the vessels of their body and secundines. Med. Ed. Ed. vol. 16. p. 193, 204, 206.

Liquor is found in the thorax of *fœtus*, which Mr. Ford notices to be supplied by the thymus. See Mem. de l'Acad. des Sciences. 1733.

It is a question, from what the great act by which the change is made in animals, from the state of *fœtus*, to that of man, is derived, and the other qualities of animal life in the larger degree. M. Duverney observed this in the *fœtus* of a common snake, she broke the egg of one of these animals, at a time when it was just ready for hatching, and the young snake fell not rolled in a spiral, at first quite flat and motionless; but it had no sooner breathed three or four times than it began to perform all the motions of animal life, in the most nimble and active manner.

It is a question, from what the blood of a *fœtus* is derived. See BODEN.

Mr. Wells, a late writer, has gone a great way towards drawing light to the system of Glisson and Harvey, and that of Mead, with regard to the circulation of the blood in the *fœtus*. He affirms, that it neither does, nor can pass from the right auricle to the left, nor from the left to the right, through the foramen ovale. In support of this assertion he observes, that there is a synchronism in the motion of the auricles of the heart, the systole and diastole happening, precisely, at the same moment of time; and, therefore, the force that is necessary to make the blood pass from one auricle into the other, cannot exist itself during the systole, because the two auricles are equally and simultaneously contracted, and throw out the blood with which they are filled; nor can it be exerted during the diastole, because the two auricles are then relaxed, and receive obstinate blood from whatever part a current is subsequently there is no moment of time in which the blood can pass from one auricle into the other. In searching the heart of a new-born child, Mr. Wall discovers, that the structure of the organ of circulation in the *fœtus* is very different from what it was commonly imagined to be; for he found, that the aperture on the left side of it was very different from that on the right; the first being formed by that which foreigners call the *arcus of Vieussien*; and the valve of Eustachius, and the second being derived from the same are and the valve of the foramen ovale; and from a further examination of this structure it appeared, that the auricles had no communication with each other, but were separated by the inferior trunk of the vena cava; the aperture which is discernible in the right auricle being nothing more than the orifice of the cava, which effectuates its insinuation into that auricle, while the aperture that is seen on the left side, and called the foramen ovale, is no more than another orifice of the same vein, which has its insinuation in the left auricle. Thus both the auricles communicate with the vena cava, but have no communication with each other, and the foramen ovale is only the left orifice of the inferior vena cava.

In order to determine the direction which the blood follows in its circulation we are to consider, first, in the vena cava, opens itself by its two orifices in the two auricles or flanges of the heart, the blood, which it contains must, be conveyed partly into the right auricle by the right orifice, and partly into the left auricle by the left orifice; and the quantity of blood, which discharges itself into the right auricle, mixing itself there with the blood of the superior vena cava, flows directly from thence into the right ventricle of the heart; nor can the least drop of blood, that has once got into the right auricle, repass from thence to the left; and the quantity of blood, which passes from the inferior cava, through its left orifice, into the left auricle of the heart, contributes to disengage the lungs, by turning its direc-

tion from the right auricle, the right ventricle, and consequently from the lungs, which, being destitute of respiration, could not have transmitted this blood, as facilitated in passage. That portion of blood, therefore, moving itself in the left auricle with that of the pulmonary veins, proceeds directly to the left ventricle, and from thence into the aorta; from whence it takes its course away in different channels through the whole body, without touching the lungs. Nor. Comment. Acad. Scient. Imp. Petropol. vol. 11. 4755.

The *fetus* often dies in the womb. This is discovered to be the case by the following symptoms: the mother becomes languid and weak, and is subject to frequent faintings. She complains also of dying heats and chilliness, succeeding one another at short intervals, and of straits of the præcordia, anxiety of mind, and vertiginous distensions of the head. The breasts, though before distended and hard, grow flaccid on this, and have an abundance of a thin watery serum in them. The *fetus* is not perceived to move, and the belly hangs upon the thighs with an uncommon dead weight, and is affected with a remarkable coldness.

The death of the *fetus* is often owing to a remarkably puerile state of the mother; and yet more frequently to her violent passions, whether of grief, anger, fear, or any other kind. The morbid constitution of the mother may also occasion it, be it almost of any kind whatever, and also habitual diarrhoea. But the death of the *fetus* is most frequently occasioned by the bad success of late-term-pain, or bad assistance in them, and by its being left couched by the womb.

The expansion of the dead child is to be attempted by all the forcing medicines (such as borax, and the like) and the spirits and strength are to be kept up during the attempt, by giving stimulants in the intermediate time; but if these measures have not the desired effect, the manual operation of the man-midwife must be called in; and when the *fetus* is taken out the woman is to be treated with the utmost care in the common way of lying-in women. See DELIVERY.

Bartholin, in his treatise De Infopis. Partu Viis, relates a great many stupendous cases of *fœtus* dead and perished in the womb, the parts of which have made their way through apertures; one whereof, at the navel, was some years in coming away. And in the Philoph. Transactions we meet with the like instances; particularly of one voided piece-meal by the anus, several years after conception.

Authors give accounts of *fœtus* found in the Fallopian tubes, and others in the cavity of the belly. M. de S. Maurice, in the Memoirs of the Royal Academy of Sciences, relates the history of a *fetus* formed in the ovary of the mother, and which, at three months from impregnation, bursting the testicle, forced its way through into the epigastric region.

Others have occasioned abortion, on the opening of which a passage has been made for the *fœtus*, which has come away piece-meal.

The story of Margaret, counsellor of Holland, who is said to have been delivered of 364 *fœtus*, all alive, and afterwards baptized, passes for a fable; and yet there is a picture of this notable delivery still preserved in the church of Lofdane, as a monument of the truth thereof. Albertus Magnus gives a like instance of a woman, who brought forth 150 *fœtus*, or embryos, all formed, as big as a little finger.

FOG, or mist, a meteor, consisting of gross vapours, floating near the surface of the earth.

If the vapours, plentifully raised from the earth and waters, either by the solar or subterraneous heat, meet, at their first entrance into the atmosphere, with cold enough to condense them considerably, their specific gravity being thereby increased, their ascent will be stopped, and they will either return back in form of a dew, or of drizzling rain; or they will remain suspended for some time, in form of a fog. See EVAPORATION.

Fogs are only low clouds, or clouds in the lowest region of the air, and clouds are no other than fogs raised on high.

Ovipara viewed through fogs appear larger, and more remote than through the common air.

The fishing for herring is chiefly practised in fogs weather.

FOGAGE, in the *Fœtus* law, is task grass, not eaten in the summer.

FOIBLE, a French term, frequently used also in our language.

It literally signifies weak; and in that sense is applied to the body of animals, and the parts thereof; *una foible reins, foible sight*, &c. being derived from the Italian *foivolo*, of the Latin *foivus*, it is hominized, *pitid*.

But it is chiefly used now as substantively to denote a defect,

defect, or flaw, in a person, or thing. Thus we say, every person has his *foibles*; and the great secret consists in hiding it artfully: *princes* are gained by flattery, that in their *foibles*; the *foibles* of young people is pleasure; the *foibles* of old men is avarice; the *foibles* of the great and learned is vanity; the *foibles* of women and girls, coquetry, and an affectation of having gallants.

It is a term also used in fencing, to denote the weakest part of a blade; in opposition to the *forte*, which is the strongest.

FOIL, in *Fencing*, denotes a blunt sword, or one that has a button at the end covered with leather, used in learning the art of fencing.

FOIL, among *Jewellers*, a thin leaf of metal, placed under a precious stone, in order to make it look transparent, to improve the colour, or to give it an agreeable different colour, either deep or pale. Thus the effect of giving luster is produced by the polish of the surface of the foil, which is colourless; but if a stone is wanted to be of a pale colour, a foil of that colour must be put under it; if deep, a dark one must be laid under it.

These foils are made either of copper, tin, gold, or gold and silver together; the copper foils are generally known by the name of *Nuremberg* or *German foils*. They are prepared as follows.

Procure the thinnest copper-plate that can be got; beat these plates gently upon a well-polished anvil, with a polished hammer, as thin as writing paper; or pass them between a pair of fine file rollers, very close set; and placing them between two iron plates, as thin as possible, heat them in the fire: then beat the foil in a pipkin, with equal quantities of tartar and salt, constantly stirring them, until by boiling they become white; after which, taking them one and drying them, give them another hammering, until they are fit for use. Care however must be taken, not to give the foil too much heat, for fear of melting; neither must they be too long boiled, for fear of strutting too much salt.

The manner of polishing these foils is as follows: take a plate of the best copper, one foot long, and about five or six inches wide, polished to the greatest perfection; bend this to a long convex, lessen it upon half a roll, and fix it to a bench or table; then take some chalk, washed as clean as possible, and sifted through a fine linen cloth, until it is as fine as can be made, having laid some of this upon the roll, and wetted the copper all over, lay the foil upon it, and, with a polished stone and the chalk, polish them till they are as bright as a looking glass. After this they must be dried, and laid so secure in a tin.

The best method of preparing foils, in as to give to colourless stones, as crystals, rubies or palls, the lustre and play of diamonds, is as follows:

Take leaves of tin, prepared in the same manner as for silvering looking-glasses, and cut them into small pieces, of such size as to cover the surface of the socket of the stones that are to be set; lay three of these one upon another, and, having moistened the inside of the socket with thin gum water, and fastened it to dry, that only a slight thickness may remain, put the three pieces of leaves, lying on each other, into it, and adapt them to the surface in as even a manner as possible. When this is done, heat the socket, and fill it with warm quicksilver, which must be left in it for three or four minutes, and then gently poured out. The stone must then be thrust into the socket, and closed with it; care having been previously taken, that it may enter the socket without slipping off the tin and quicksilver from any part of the surface. The work should be well closed round the stone, to prevent the tin and quicksilver contained in the socket from being shaken out by any violence. The lustre of stones set in this manner, will continue longer than when they are set in the common way.

When colouring foils are wanted, those of copper, above described, may be either tinged with smoke, or stained or painted with some pigment or other colouring substance. The colours used for this purpose, may be tempered with oil, gummed or fixed water, or varnish: for red, in imitation of ruby, carmine, with a little lake used in longish size, or shell-lac varnish, or bright lake in oil, should be employed; for the garnet red, dragon's blood, dissolved in seed-lac varnish, may be used; and for the deeper garnet, orange lake, tempered with shell-lac varnish. For the amethyst lake, with a little Prussian blue, used with oil, or blue; where the effect of sapphires is wanted, Prussian blue in oil, and spread on the foil more or less thick, according to the lightness or deepness of the colour required; for the eagle marine, common verdigris with a little Prussian blue, tempered in shell-lac varnish, should be used; for a full yellow, yellow lacquer; and for the lighter colour of topazes, the burnish and foil itself will serve, without any addition. For a deep green, the crystal of verdigris, tempered in shell-

lac varnish; but for the emerald, a little yellow lacquer should be added. See DOUBLETS. Handmaid to the Arts, vol. ii. p. 333, &c.

FOIN, or **FOYER**, among *Looking-glass-makers*, a sheet of tin, with quicksilver, or the like, laid on the back-side of a looking glass, to make it reflect. See FOLIATING. The word is formed of the Latin *fovere*, to feed.

FOLLING, among *Hunters*, the footing and treading of deer, which remains on the grass, but scarce visible.

FOLCLAND. See FOLK-LAND.

FOLDAGE and **FOLK-COVERS**. See FALBAGE.

FOLD-ROD, among *Sparfines*, a sort of net with which small birds are taken in the night; there are two sizes of it; the best must be managed by one man, but the largest must be carried by two, and used thus: let the net be fixed on both sides to two strong poles about twelve feet long, each man holding one of them; let a third carry lights behind them, at the distance of two yards; the net should be carried between the wind and the birds, which rest on their perches with their backs against the wind; another person, who bears the bushes on the other side of the hedge, will drive out the birds towards the light.

FOLD-ROD, in *Law*. See FALBAGE.

FOLDS, in the *Manufactures*. See CLOTH, &c.

FOLDS of the *droptery*, in *Painting*. See DAPHER.

FOLDING of *leaves*. See SHEET.

FOLIA, in *Botany*, is used for the leaves of plants, and also of flowers, but particularly the former; the leaves of flowers being more properly called PETALS.

FOLIACEUM *reparation*, in *Anatomy*, is that extreme of the *FALLOTTIAN* tube, next the ovary; and which is expanded like the mouth of a trumpet, and inversed with a sort of fringe.

FOLIAGE, a cluster or assemblage of flowers, branches, leaves, &c.

FOLIAGE is generally used for representations of such flowers, leaves, branches, roots, &c. whether natural or artificial; used as enrichments on CAPITALS, FRASES, PEDIMENTS, &c. See TAB. ARCHIT. fig. 12.

FOLIATE, in the *Higher Geometry*, a name given by some to a curve of the second order, expressed by the equation $x^2 + y^2 = ax$, being one species of defective hyperbolas, with one asymptote, and consisting of two infinite legs enclosing one another, and forming a sort of leaf.

FOLIATING of *looking-glasses*, is the spreading a composition of something, which will firmly adhere to the back of the glass, and there reflect the image.

This composition is called the *foil*, and is usually made with quicksilver, mixed with tin, and some other ingredients.

For the method of *silvering* looking glasses, see LOOKING-GLASS.

In Philosophy. Trans. N° 245. we have a method of *falling* globe looking-glasses, communicated by Sir R. Southwell. The mixture is of quicksilver and bismuth, of each three ounces; and tin and lead, of each half an ounce; to the two last throw on the marshall, and afterwards the quicksilver, stir them well together over the fire; but they must be taken off, and be towards cooling before the quicksilver be put to them.

When you use it, the glass should be well heated, and very dry, but it will do all when it is cold, though best when the glass is heated.

Mr. Boyle's method, which he prefers to any he ever met with in prior, is this: take tin and lead, of each one part; melt them together, and immediately add of good tin glass, or bismuth, two parts; carefully stir on the dross; then take the crucible from the fire, and, before the mixture grows cold, and thereto mix parts of clean quicksilver, and having stirred them all together keep the fluid in a new clean glass. When you go to use it, stir purge it, by draining it through linen, and gently pour some ounces into the glass to be *silvered*, through a narrow paper funnel, reaching almost to the glass, to prevent the liquor from flying to the sides. After this, by accurately inclining the glass every way, and endeavour to descend to the internal surface, which done, let it rest for some hours; then repeat the same operation and so continue at times, till the liquor is slowly passed over, and equally fixed to the whole superficies; which may be assisted by exposing the glass to the eye between that and the light. Boyle's Works, vol. ii. p. 126.

FOLIATION, in *Botany*, &c. is used by Dr. Green, to express the assemblage of the *FOLIA*, or *SEPALA*, of a flower.

The *foliation* is the most conspicuous part of flowers, being that collection of fugacious, coloured leaves, which constitutes the compass, or body of the flower. It is of great use in the generation and preservation of the young fruit, or seed; it saturates a fine juice, to nourish it in the uterus, or pill.

In some species, as apricots, cherries, &c. it likewise serves

to guard the young tender fruit from the violence of wind, weather, &c. for this, being of a very tender and pulpy body, and coming forth in the colder times of the spring, would not be injured by the extremities of weather, if it were not thus protected, and lodged within the flowers.

Before the flowers open, the *folium* is curiously and artfully folded up in the calyx or perianthium.

Dr. Grew enumerates several varieties of their foldings, viz. the *clipeatus*, as in roses; the *ovatus*, as in the bistaria flow; also the *imbricatus*, as in pea blossoms; the *emarginatus*, as in marigolds; and the *rotundus*, as in the ladies' bower.

FOLIUM, or rather **FOLIUM**, in books of account. &c. signifies page.

Thus *folio 7.* written abridgedly *F° 7.* denotes the seventh page, &c.

Folio recto, or *F° R°*, expresses the first side or page of a leaf.

Folio verso, or *F° V°* the second, or back-side of the leaf.

The word is Italian, and literally signifies leaf.

FOLIO, among *Bibliothecarii*, a book in *folio*, or simply, a *folio*, is that where the sheet is only folded in two, each leaf making half a sheet.

Beneath the *folio* are the *quarto*, *octavo*, *duodecimo*, *sexdecimo*, *quingentesimo*, &c.

FOLIS, or **FOLLIS**, anciently signified a little bag or purse; whence it came to be used for a sum of money, and very different sums were called by that name: thus, the scholiast on the *Basilics*, mentions a *folis* of copper which was worth but the twenty-fourth part of the *MILIARENUS*; the glossæ nomica, quoted by Gronovius and others, one of a hundred and twenty-five *miliarenæ*, and another of two hundred and fifty *denarii*, which was the ancient *clisterium*; and three different sums of eight, four, and two pounds of gold, were each, called *folis*. According to the account of the scholiast, the ounce of silver, which contained five *miliarenæ* of sixty in the pound, was worth a hundred and twenty *folis* of copper.

The glossographer, describing a *folis* of two hundred and fifty *denarii*, says it was equal to three hundred and twelve pounds six ounces of copper; and as the *denarius* of that age was the eighth part of an ounce, an ounce of silver must have been worth a hundred and twenty ounces of copper; and, therefore, the scholiast's *folis* was an ounce of copper, and equal to the glossographer's *nummus*. But as Constantine's copper money weighed a quarter of a Roman ounce, the scholiast's *folis* and the glossographer's *nummus* contained four of them, as the ancient *nummus* contained four *asses*. See Phil. Trans. vol. 11. p. 515, &c.

FOLIUM. See LEAF.

FOLIUM brachiarum, the leaf of the gill, a term used by some of the ichthyologists, to express that part of the gills which looks red and fringed. The gills of fish are composed of certain bony circles, which are formed on the convex side with a great number of lamina; these serve to receive the ramifications of the arteries, and are called the *folium* or leaf of the gills. The aorta or great artery reaches no farther than this part in fish. It has no descending trunk, but every part of the body is supplied by a large vasa trunk, formed by the joining of the several smaller trunks of the lateral circles of the gills.

FOLIUM coryphatum, or clove-leaf. See CLOVE-tree.

FOLIUM Indicum, or *Indum*, called also *TAMALAPATRA*, and *MALABATHRUM*; a leaf brought from the Indies, growing chiefly about Cambray, produced by a tree not unlike the lemon-tree, used in the composition of Venetian-treacle.

FOLK-LAND, in our ancient Saxon customs, denoted *conventus* or land.

In opposition to these, charter-lands were called *hithland*, or *non-land*.

Fundus sine fructu pignus (says Sommer) *estiam pignus*

animum. *Est hithland* (fructus) *animum*; terra popularis.

FOLKNOTE, **FOLKNOTE**, or **FOLKNOTE**, among our Saxon ancestors, signified any popular or public meeting of all the folk or people of a place, district, or the like; e. g. of all the tenants of a court-leet, or court-baron; or of all the free men of the county; or of all the barons, of a kingdom.

The word, says Stow, is still in use among the Londoners, and signifies *agere ad unum civitatis consensum*, an assembly of all the citizens. Manwood says it is the court-holden in London, wherein all the folk and people of the city did complain of the mayor and aldermen for any misgovernment.

Sommer, in his Saxon Dictionary, makes *folnote* to denote a general assembly of the people, for doing fealty to the king, and considering and ordering matters of the commonwealth; whence some date the origin of parliament.

Omnes præter regem, & milites & liberi homines universi tunc regni Britannia, facere debent in plene folnote fidelitatem domino regi, eorum episcopis regi. In Leg. Edw. Confess. cap. 33. Et amplius non fit in hysting, miskenings, i. e. speaking amiss; neque in folkenote, neque in alio placito infra civitatem. Charta H. I. pro London. De Cange.

When such assembly is made in a city, it may be called a *burghmote*; when in the county, a *shiremote*.

Com aliquid vero inspiratum & malum contra regem vel contrarium regis emerjisset, statim debent, pulvis campanis, quod Anglice vocatur motbell, convocare omnes & universos, quod Anglice vocatur folnote. &c. Leg. Alfred.

FOLLICULUS, among *Gardeneri*, the seed-vessel, case, coat, husk, or cover, wherewith several kinds of seeds and fruits are inclosed.

FOLLICULUS fellis. See GALT-bladder.

FOLLY, according to Mr. Locke, consists in the drawing of false conclusions from just principles; by which it is distinguished from madness, which draws just conclusions from false principles.

But this seems too confined a definition; *folly*, in its most general acceptation, denoting a weakness of intellect or apprehension, or some partial absurdity in sentiment or conduct.

FOMAHANT, or **FOMALHAUT**, in *Astronomy*, a star of the first magnitude, in the water of the constellation *AQUARIUS*.

FOMENTATION, a liquid medicine, applied to any diseased part, to resolve, dilute, soften, allay, fortify, or constringe the same.

Fomentation are either simple or compound.

FOMENTATIONS, compound, are decoctions of roots, leaves, flowers, and seeds, made in common water, or other proper liquor, to which are sometimes added salts, exsiccants, &c.

To use, or apply them, they dip a hot linen cloth, or flannel, in the liquor, and spread it on the part affected. There are also *fomentations* made another way, viz. by boiling certain drugs in linen bags, and then applying them, bags and all, on the part.

There is also a sort of dry *fomentations*, being bags filled with medicines, but not boiled, only sometimes sprinkled with a little wine or brandy.

FOMENTATIONS, simple, are those made with luke-warm water, milk, oil, oxyrate, or the like liquors.

Fomentations are also called *local baths*, or partial bathing; because, being applied on a diseased part, they have much the same effect as a bath, or half-bath, has on the whole body.

Fomentations have different names, according to the preparations of which they consist, and the uses to which they are applied. Thus, the *anodyne fomentation*, used for relieving acute pain, is composed of white poppy-head, two ounces; elder flowers, half an ounce; which are boiled in three pints of water till one pint is evaporated, and then the liquor is strained out: the aromatic *fomentation* is prepared by boiling half an ounce of Jamaica pepper in a pint of red wine for a little while, and straining out the liquor; this is used both for external and internal complaints. Colics and disorders of the bowels are often abated by fomenting the shomen and region of the stomach with this warm liquor. The common *fomentation* is made by slightly boiling the dried tops of wormwood and camomile flowers, of each two ounces, in two quarts of water, and pouring off the liquor, to which may be added such quantities of brandy or spirit of wine as the particular case may require. The emollient *fomentation* consists of one ounce of camomile flowers; elder flowers, and sweet fennel seeds, of each half an ounce, boiled for a little while in two quarts of water, and strained, with the addition of spirit of wine, &c. The strengthening *fomentation* is prepared of oak-bark, one ounce; granite, peel, half an ounce; alum, two drams; and smith's forge water, three pints: the water is boiled with the bark and peel till one third is consumed, and in the remaining decoction, strained, the alum is to be dissolved. This astringent liquor may be applied to foment weak parts, and also used internally.

FONCEAU, in the *Manège*, is the bottom or end of a cannon-butt-mouth; that is, the part of the butt that joins it to the banquet. See CHAPTER IV.

FONGITES, a name given by the writers of the middle ages to a stone famous for its imaginary virtues. Authors are very vague in their descriptions of it; some describing it as pellicid and colourless, like crystal; others, as opaque and of a flame-colour; and some say, that it was partly of one and partly of the other of these colours. It is said to mitigate pain, on being held for some time in the hand.

FONT, or *supra* **FONT**, a stone or marble vessel, at the lower-end of a parish-church, serving to hold water to be used in administering the sacrament of baptism.

A baptisml

A baptismal *font* was anciently the character of a parish church.

Its place, at present, is at the bottom of the church, or in a little chapel within the church. Anciently it was placed in a little church, distinct from the great one, though near to it, called the *BAPTISTERY*.

By the eighty-first canon it is required, that there shall be a *font* of stone in every church and chapel, where baptism is to be administered, the same to be set in the ancient usual places; in which only *font* the minister shall baptize publicly.

Font, in the *Art of Printing*, denotes a complete assortment of letters, accents, &c. used in printing. See **FOUND**.

FONTANELLA, in *Anatomy*, imports the quadrangular aperture found betwixt the os frontis, and ossa incisiva, in children just born; which is also called *font pallidus*.

FONTEVRAUD, or **FRONTEVAUX**, order of, in *Ecclesiastical History*, a religious order instituted by Robert d'Arbrissel, about the latter end of the eleventh century, and taken under the protection of the holy see by pope Pascal II. in 1106, and confirmed by a bull in 1113, and invested by his successors with very extraordinary privileges. The chief of this order is a female, who is appointed to inspect both the monks and nuns. The order is divided into four provinces, which are those of France Aquitaine, Auvergne, and Bretagne, in each of which they have several priories. Bayle.

FONTICULUS, or **FONTANELLA**, in *Surgery*, a general name for *ISSUES*, *ARTERS*, and the like other small artificial discharges.

The word is a diminutive of *font*, fountain, or spring.

FONTINALIA, or **FONTANALIA**, in *Antiquity*, a religious feast held among the Romans, in honour of the deities who presided over fountains, or springs. Varro observes, that it was the custom to visit the wells on those days, and to cast crowns into fountains. Scaliger, in his conjectures on Varro, takes this not to be a feast of fountains in general, as Festus insinuates, but of the fountain which had a temple at Rome, near the Porta Capena, called also *Porta Fontinalis*: he adds, that it is of this fountain Cicero speaks in his second book De Legibus. The *fontinalia* were held on the 13th of October.

FONTINALIS, in *Botany*, the name of a genus of mosses of the *cryptogamia* class; the characters of which are these: the capsules are sessile, or have either no pedicels, or extremely short ones; they are not naked as in the sphagnum, but are covered with calyptra, and are included besides in a membranous bulk, by which last particular they are distinguished from the hypnum, bryum, and other mosses which produce capsules. Tab. XIV. *Botany*, N^o 9.

There are only five known species of this genus. Linnæus enumerates only four species. Dillen. Hist. Moss. p. 236.

FOOD, or **ALIMENT**, is whatever matter is taken in at the mouth, digested in the stomach, and other viscera and converted into the matter of the body, to repair or supply what is spent, or wanting.

The operations which the *food* undergoes, before it becomes a part of our body, are, 1. Mastication. 2. Deglutition. 3. Concoction. 4. Chylification. 5. Sanguification. 6. Assimilation.

Food is of two kinds, viz. *esculents*, or *meat*; and *potulenta*, or *drink*.

The first *food* of our great forefathers were water, and the spontaneous productions of the earth; with which also many whole nations sustain themselves to this day.

The variety of *foods*, it seems, does not make any difference in the substance, or actions, of the bodies sustained thereby; the viscera having a power of altering and assimilating them, however heterogeneous, into one similar substance, like themselves.

The difference in *foods* consists principally in this: that some are more easily digested, and assimilated than others; and that some afford more nutritious juice than others; and to this end it is, that the divers kinds of dressings have been invented, viz. to dispose the matter *food* more easy and plentiful assimilation.

The best, most simple, and light of digestion, are, the *foods* prepared of frumentaceous and leguminous seeds; as wheat, rye, barley, oats, and maize; dried, ground, fermented, baked, &c. peas, beans, vetches, &c. also green plants, and pot-herbs; as lettuce, beet, parsley, &c. truit, as apples, pears, berries, plums, cherries, &c. and the lean parts of animals, birds, fishes, insects, &c. prepared by boiling, baking, stewing, &c.

And yet, for different intentions, different kinds of *food* are required. Thus hard, dry, thick, heavy, sculent *foods*, are best for those whose viscera are strong, digestion quick, &c. and soft, light, humid, simple *foods*, to such are pernicious. Again, to the weak, vascular, fluid, and sedentary, these *foods* are best, which are either by art, or nature, the nearest to chyle; as milk, broth, &c.

Vol. II. N^o 137.

Where the temperature inclines to acidity, these alkaline *foods* are the more suitable; and acids, where the constitution inclines to be alkaline.

Some will have it, that iron, metals, minerals, &c. may by a proper preparation, become *food*; on which account decoctions of gold, chalybeate, &c. are extolled; but it is certain, that no such matters can ever be assimilated, and become part of our body; they may act, indeed, on the blood, and the blood-vessels, by their weight, impetus, &c. and, on that account, may be of use in medicine, but not as *food*.

A due regulation of the quantity and quality of our *food*, and a nice adjustment thereof to the conculsive powers, would be of the utmost consequence to health and long life.

What we expend in motion, exertion, effluvia, &c. is but a determinate quantity; and the supply should only keep pace with the expense: a just proportion of the two would, probably, preserve us from acute distempers, as a certainly would from chronic ones; such, or all of which proceed from replication, as appears from their being cured by evacuation.

The qualities of *food*, as easiness, or difficulty, of digestion, Dr. Cline thinks, may be determined, in all cases, from these three principles.

1. That those substances which consist of the grosser parts, are hardest of digestion; because their constituent parts touch in the most points, or have the greatest quantity of contact, upon which their cohesion depends.

2. That those substances whose parts are brought together with greater force, cohere proportionally closer, and are the more difficultly separated.

3. That salts are very hard to be digested, because united by plane surfaces, under which they are always comprehended; hence, in the last stages of the circulation, where it is slower, they readily shoot into larger clusters, and so are hard to be driven out of the habit.

From these principles that author infers, that such vegetables and animals as come soonest to their growth, are easier of digestion than those long in attaining to maturity; the smallest of their kind, sooner than the larger; those of a dry, fleshy, and fibrous substance, sooner than the oily, fat, and glutinous; those of a white colour, sooner than those of a redder; those of a soft, mild, and sweet, sooner than those of a rich, strong, poignant, aromatic taste; land animals, than sea animals; animals that live on light vegetable *food*, than those on hard and heavy *food*; plain dressed *food*, than what is pickled, salted, baked, smoked, or otherwise high seasoned; and boiled meat sooner than roast, &c.

The same author adds, that abstinence and exercise must concur with the due *food* for the preservation of health; and that where exercise is wanting, as in studious persons, the defect must be supplied by abstinence. See **DIET**.

Physicians have attempted to determine the healthful quantity of *food* for a human body. Some say, that in winter, where the perspiration of an unexercised person is only equal to the urine, the diet for twenty-four hours ought not to exceed four pounds, or four pounds and a half. In summer, the diet may be six pounds and a half, which may be carried off without the help of exercise, when the air is hot and dry.

Dr. Bryan Robinson thinks, that if the quantity of *food* be such as to make the perspiration and urine of a natural day always nearly equal, and the morning weight of the body always nearly the same, that quantity is the truly healthful quantity of *food* for grown bodies, which use but little exercise.

The quantity of *food* necessary to keep a grown body in health, will be better and more easily digested, when it is so divided as to make the meats equal, than when they are very unequal. The distance between one meal and another should bear some proportion to the largeness of the preceding meal.

The same author thinks, that good and constant health consists in a just quantity of *food*, and a just proportion of the meat to the drink; and that to be freed from chronic disorders contracted by intemperance, the quantity of *food* ought to be lessened, and the proportion of the meat to the drink increased more or less, according to the greatness of the disorders; and that both the quantity of *food*, and the proportion of meat to drink, ought to be such as shall make perspiration and urine nearly equal at all seasons of the year. See his *Dissert. on the Food and Discharge of Human Bodies*, p. 6.

FOOD OF PLANTS. What is generally understood by this term is such matter, of whatever kind, as being added and united to the first flames of plants or plankton, at their sowing, or to their roots, and thence to their trunks and other parts afterwards, gives them their increase, or, in other words, it itself the matter of that increase.

great art of the husbandman is the giving this *food* to plants, in the best manner, and to the greatest advantage. But before he can expect to arrive at any true knowledge in this article, it is necessary that he should know what this *food* or matter of nourishment is. There are five things generally allowed to contribute to the growth and increase of plants; these are nitre, water, air, fire, and earth; but it has been much disputed which of all these it is that increases, or is properly the *food* of the plant. Many people lay much of the acid spirit residing in the air; but as this is sharp enough to corrode iron bars, it is too sharp to be fit for nourishing tender plants. As to nitre, it is said to nourish them; but its true office is not actually nourishing, but preparing other things to nourish them. Nitre applied to the root of a plant will kill it; but at a distance, so attenuated, cuts and divides the viscous matters found in the earth, that after this they are fit to nourish plants, though they were not before. Water has been thought by some the only *food* of plants; but Van Helmont's famous experiment, usually brought to prove this, is nothing, for the water contains earth, and therefore never given to a plant as water alone.

Air, because of its elasticity, is necessary to the increase of plants, but it is not that increase, though Bradley and others have taken great pains to prove that it is so. As to fire, we are very well assured indeed, that no plant can live without heat; but though different degrees of it are necessary to different plants, yet none can live in actual fire; nor has fire ever been thought the *food* of plants except by Mr. Lawrence, and some of the metaphysicians. This author indeed says, plants are true fire-eaters, and others explain away the meaning of the phrase by defining that fire to be only the minutest particles of earth put in motion; if this be the case, probably enough the doctrine may be true. But as some have maintained, earth alone is the true *food* and matter of increase of plants. Every plant, they say, is earth, and the growth and increase of that plant is only the addition of more earth to it, in the same form. Nitre and other salts, as those of dung, &c. prepare, attenuate, and divide the earth, destined for the increase of vegetables; water and air move it by conveying, and fermenting it in the juices; but earth itself still is the *food*. When the additional earth is once assimilated to the plant, it becomes a part of it, and remains for ever with it; but let water, air, and heat, be taken away, and the plant remains a plant still, though a dead one.

The excess of the other things proves, that they are not the proper *food* of the plant, by destroying not nourishing it. Too much nitre or other salts corrode and kill the plant, too much water drowns it, too much air dries the roots of it, too much heat burns it; but too much earth a plant can never have, unless wholly buried under it, so as to exclude the necessary action of the rest of the assistant articles. See PLANT.

FOOL, according to Mr. Locke, is one who makes false conclusions from right principles; by which he is distinguished from a madman. See FOLLY.

Dr. Willis relates, that upon dissecting a *fool*, the principal differences found between him and a man of sense, were, that the brain was smaller; and that the cerebral plexus, formed of the intercal nerve, whereby the correspondence between the brain and heart is effected, was less, and sent forth fewer branches to the heart, &c. *Nervor. Descript. & Uf. cap. 26.*

FOOT's bones, in BEasts. See OSSEMENT.

FOOT, a part of the body of most animals, whereon they stand, walk, &c.

Animals are distinguished, with respect to the number of *feet*, into bipedes, q. d. *two-footed*; such are men and birds; quadrupedes, q. d. *four-footed*; such are most land animals; and multipedes, q. d. *many-footed*; as insects. The reptile kind, as serpents, &c. have no feet.

Insects have twelve *feet*; spiders, mites, and polypuses, eight; flies, grasshoppers, and butterflies, have six *feet*. Galen has several good observations on the wise adjustment of the number of *feet* in men and other animals, in his book De Uf. Part. lib. iii.

The *four-footed* of the mole are admirably formed to dig, and scratch up, the earth, and make way for its head, &c. in water fowls, the legs and *feet* are excellently adapted, to their respective occasions, and numbers of living; in such as are to wade in rivers, the legs are long, and bare of feathers a good way above the knee; their toes also are broad; and in such as beat, the name of *web-footed*, two of the toes are somewhat staked, that they may not easily sink in walking upon boggy places.

Others, which are to swim, are *web-footed*; i. e. have their toes webbed together as in the goose, duck, &c. and it is pretty enough to observe, how artfully they will gather up their toes and *feet*, when they withdraw their legs, or go to take their strokes in swimming; and again

expand, or open, the whole *feet*, when they press upon, or drive themselves forward in the water.

FOOT, in *Anatomy*. The *great foot* denotes the whole extent from the jointure of the hip to the tip of the toes; as the great hand does the whole from the shoulder to the fingers ends.

The *pes magnus*, or *great foot*, is divided into the thigh, the leg, and the *foot* properly so called.

Its bones are, the femur, or thigh-bone; the TIBIA, the PATELLA, and FIBULA, for the leg; and those of the tarsus, metatarsus, and toes.

Its arteries are branches of the crural artery, and its veins terminate in the crural vein. Of these there are five principal ones; viz. the SAPHENA, great and little iliac, the MUSCULUS, POPLITEA, and SURALIS.

FOOT, properly so called, or the *lifer foot*, denotes only the extremity of the leg, consisting of three parts; viz. the tarsus, the space from the ankle to the body of the foot, answering to the wrist in the hand; metatarsus, the body of the *feet* to the toes; and digit, or toe. Each of these parts consist of a great number of bones; as the calcus, talus, calciformis, and cubitus. The bottom of all is called the sole, or *plantæ pedis*. See TARSUS, &c.

FOOT, cartilages of the. The *allogaba* is covered by three cartilages; the first covers the three surfaces which make the convex part and sides of the pulley; the second the concave surface of its inferior part, and the third the convex surface of its inferior part, being continued over the inferior part, so far as to form three other small surfaces; one of which is not articular in a strict sense. The first of these cartilages is for the articulation of this bone with the tibia and fibula, the second for the *excalcis*, and the third for the *scaphoides*; two of the inferior surfaces formed by the continuation of the third cartilage, are for the articulation of this bone with the *scaphoides*; and the third contributes to the formation of a channel for the passage of a tendon.

The *scaphoid* has four cartilages, of which three are superior, one large, and two small, for its triple articulation with the *allogaba*; the fourth is inferior for the *scaphoides*. And to these must be added a small thin cartilage of a kind of ligamentary substance, under the tubercle, on the outside of this bone. The *scaphoides* has two cartilages; one posterior, for its articulation with the *allogaba*, and one anterior, divided into three parts for the three *scaphiformis*.

The *scaphoides* has two remarkable cartilages, one posterior, for its articulation with the *scaphoid*; the other anterior, lying in two planes, for its articulation with the two last metatarsal bones; it has likewise a cartilage on the inside for the *scaphiformis*, which is next to it, and one on the lower part, covering an oblique eminence situated there.

The three *scaphiformis* have each of them a posterior cartilage for their articulation with the *scaphoides*; and one anterior for the three first metatarsal bones; they have likewise small cartilaginous surfaces on their lateral sides for their articulation with each other; and besides, the first and third bones are joined thereby to the lateral parts of the basis of the second metatarsal bone, and the third to the *scaphoides*. The bases and heads of the metatarsal bones are covered with cartilages. The phalanges also have, in the same manner, cartilages at their bases and heads, except at the heads or extremities of the last. The sesamoid bones are covered with cartilages on that side, by which they slide on other bones; but great caution is required not to confound the remains of tendons, ligaments, and aponeuroses, with the true cartilages, particularly on the posterior part of the *scaphoides*. Winslow's Anatomy, vol. i. p. 132, &c.

FOOT, ligaments of the. The *feet* being made up of many bones, must necessarily, besides those ligaments, by which it is tied to the bones of the leg, have several others to connect not only the three parts of which it is composed, but also the particular bones of each part to one another. In each ankle there are three ligaments for their articulations with the *feet*; one anterior, one middle, and one posterior. The ligaments of the inner ankle are all fixed to the inside of the *allogaba*; the anterior and middle ligaments of the outer ankle are more or less broad, and are fixed on the outside of the *allogaba*; the posterior, which is the narrowest, and pretty thick, is chiefly fixed in the outside of the great portion of the *scaphoid*. All these ligaments lie on the outside of the capsula, which surrounds the articulation of the *allogaba* with the bones of the leg. The ligaments by which the bones of the tarsus are connected to one another, are short, flat, of different breadths, and run from one bone to another, in different directions. Some of these are common to several bones, and others belong only to two. The *allogaba* is tied to the other bones of the tarsus by several true ligaments; so the inside of the *scaphoid*, by one

which comes from the lateral *apophysis* of the *scapula*, in inequality on its hinder part, and is fixed again to the inferior internal tuberosity of the body of the *astragalus*, to the outside of the same bone, by two ligaments which come from the edge of the oblique inferior depression of the *astragalus*, and afterwards separating a little, are fixed in the outside of the great *apophysis* of the *scapula*, one forward, which seems to send off a small portion to the *scapula*, and the other backward, of different breadths; to the *scapula* superiorly by a ligament, which goes from the neck of the *astragalus*, to the upper part of that bone, and from thence is extended to the middle of the *scapula*; to the same bone internally by two ligaments, one of which is a continuation of that which goes from the lateral *apophysis* of the *scapula*; the other is near the same production, being partly covered by the former, and fixed in the tuberosity of the *scapula*; to the *scapula*, by a ligament which comes from the oblique inferior depression of the *astragalus*, and is fixed in the oblique superior depression of the *scapula*; and to these, the principal ligaments of the *astragalus*, several smaller may be added, which are usually seen, and increase the number very greatly.

The capsular ligaments go very little farther than the edges of the articulations of this bone with the rest; they adhere very closely to the true ligaments, and are covered and hid by them. The *scapula* is connected to the *scapula*, by a continuation of the ligament that goes from its lateral internal *apophysis* to the cartilaginous production of the *astragalus*, by a ligamentary plane, which goes from its great *apophysis*, to the inferior part of the *scapula*; and by a narrower ligament, which goes from the superior internal part of its great *apophysis*, and ends in the nearest part of the circumference of the *scapula*. It is connected to the *scapula*, by several ligamentary *fasciculi*, which go from its extremity in its superior oblique depression, to the contiguous angle of the *scapula*; by one from near the lateral external tuberosity of the *scapula*, to a part of the *scapula* near the former; by one fixed to the exterior and inferior part of the great *apophysis* of the *scapula*, to the contiguous part of the *scapula*; by a pretty broad plane, which covers the inferior part of the *scapula*, and ends in the oblique eminence of the *scapula*; and by a broader plane, which filling the lower part of the lateral concavity in the *scapula*, is chiefly inserted in the contiguous angle of the *scapula*. The capsular ligaments agree with those of the *astragalus*.

The *scapula* is tied to the *scapula* on its outside by one ligament, which connects it to the contiguous angle of that bone: on its upper part two go from it to the second and third *apophyses*; on its interior side it is joined to the convex side of the great *apophysis* by two ligaments, and on its lower, it has four; the first appears double, and goes from the tuberosity of this bone to the basis of the first *apophysis*; the second and third go obliquely to the second and third *apophyses*; and the fourth is a little transverse, being fixed in the inferior internal angle of the *scapula*.

The *scapula*, beside those already described, has ligaments which tie it above, below, and on the outside, with the third *apophysis*, and the two last bones of the metatarsus; the superior ligaments are almost equally flat, the inferior irregularly thick, and stronger than the superior. The three *apophyses* are connected together on their upper part by particular ligamentary planes, which go more or less transversely, from one bone to another, being all joined to one common ligamentary plane which covers their three bones, and also the *scapula*; they are also connected by ligaments to the three first bones of the metatarsus.

The bones of the metatarsus are connected together by their bases and heads; the ligaments which go between the bases are superior and inferior; the superior small and flat, the inferior strong and thick. Those between their heads have nearly the same disposition, but the inferior have this peculiar to them, that by filling up the spaces between the heads, they keep them at some distance from one another; the inferior portions are fixed in the angles at the lower part of each head, and are strengthened by their union and intertexture with the *apophyses plantaris*. Winslow's Anatomy, vol. i. p. 224, &c.

FEET, bathing of the. The uses of warm bathing in general, and of the *pediluvium* in particular, are so little understood, that they are often preposterously used, and sometimes as injudiciously abandoned from.

In the Medical Essays of Edinburgh, we find an ingenious author's opinion of the warm *pediluvium*, notwithstanding that of Boerhaave, Boerhaave, and Hoffman, to the contrary, to be, that the legs becoming warmer than

before, the blood in them is warmed; this blood rarefying, dilends the vessels; and in circulating imparts a great degree of warmth to the rest of the mass; and there is a portion of it constantly passing through the legs, and acquiring new heat there, which heats, in the course of circulation, communicated to the rest of the blood; the whole mass rarefying, occupies a larger space, and of consequence circulates with greater force. The volume of the blood being thus increased, every vessel is dilended, and every part of the body feels the effects of it; the distant parts a little later than those first heated. The benefit obtained by a warm *pediluvium* is generally attributed to its making a derivation in the parts immersed, and a revulsion from those affected, because they are relieved; but the cure is performed by the direct contrary method of operating, viz. by a greater force of circulation through the parts affected, removing what was stagnant, or moving too sluggishly there. Warm bathing is of no service where there is an insurmountable obstruction, though, by its taking off from a spasm in general, it may seem to give a moment's ease; nor does it draw from the distant parts, but often bursts by pushing against matter that will not yield with a stronger impetus of circulation than the stretched and diseased vessel can bear; so that where there is any suspicion of scirrhus, warm bathing of any sort should never be used. On the other hand, where obstructions are not of long standing, and the impacted matter is not obstinate, warm baths may be of great use to relieve them quickly. In recent colics, with slight humoral peripneumonies, they are frequently an immediate cure. This they effect by increasing the force of the circulation, opening the skin, and driving freely through the lungs that lenient which stagnated or moved slowly in them. As thus conducing to the resolution of obstructions, they may be considered as febrile and safe fevers; and in using them we imitate nature, which by a fever often carries off an obstruclive cause of a chronic ailment. Boerhaave, Boerhaave, and Hoffman, are all of opinion, that the warm *pediluvium* acts by deriving a larger quantity of blood into the parts immersed. But arguments must give way to facts; the experiments related in the Medical Essays seem to prove to a demonstration, that the warm *pediluvium* acts by rarefying the blood.

A warm *pediluvium*, when rightly tempered, may be used as a life cordial, when circulation can be roused, or a gentle fever raised; with this advantage over the cordials and sudorifics, that the effect of them may be taken off at pleasure. Med. Ess. Edinb. 4to. vol. i. p. 237, &c.

Palluvia are sometimes used in the small-pox; but Dr. Stevenson thinks they frequently tumorous operations render it at best of very doubtful efficacy; and he therefore prefers Mout. Martin of Lausanne's method of bathing the skin, not only of the legs, but of the whole body, with a soft cloth, dipped in warm water, every four hours, till the eruption; by which means the pustules may become universally higher, and consequently more life. Med. Ess. Edinb. 4to. p. 248.

FOOT, bleeding in the. Bleeding in the foot is an operation of very old standing, and has been used by the oldest physicians, for disorders of the head and breast, and for obstructions of the menses, and habitual discharges by the hemorrhoidal veins. It has been of old supposed, that the bleeding from the *phlebotomy* was more particularly serviceable in some cases, and from the cephalic in others; but this is now known to be highly erroneous, and the surgeon is always to take that which has the safest and most efficacious. If the vein on the metatarsus or instep do not appear so fairly as might be wished, it is common to take one of those about the ankle, on the calf of the leg or ham.

The patient to be bled in the foot, must first keep both feet some time in warm water, that the veins may become turgid, and the surgeon have his choice which he will take. Having fixed upon the proper foot, the figure must be made about two fingers breadth above the ankle, and the patient must then return the foot into water. The surgeon is to kneel on one knee, and having wiped the foot dry, to put it either against his other knee, or upon a board placed over the vessel of hot water, and the vein must be held secure from slipping away, with the left hand, while the incision is made with the other. If the blood does not flow freely, the foot must be returned into the warm water, till by the reflux of the water, strength of the patient, &c. it is found to have bled enough. Heister's surgery, p. 280.

FEET, pressure of the. The bones of the foot which compose the tarsus, the metatarsus, and toes, are equally liable to fractures with the other bones, but on account of the great complication of nerves, tendons, ligaments, and membranes, fractures in this part are fully attended

ed with very bad symptoms. The bones are carefully to be replaced and secured by bandage; but fractures of the *foot*, like those of the hands, can seldom be so perfectly cured, as not to leave a stiffness or want of motion behind; if the patient should be so happy as to escape ulcers, caries, or incurable fistulae. These bad symptoms when they appear in the course of the cure, are no way to be remedied but by the amputation of the limb; nor will that indeed always secure the patient from death. Heister, p. 138.

Dr. Waltherus has given a minute description of the muscles and ligaments of the sole of the *foot*, in the Nova Act. Erudit. Sept. April, 1737.

Foot, in the *Manège*, is the extremity of a horse's leg, from the coronet to the lower part of the hoof. The four *feet* are distinguished by four different names; the two *fore-feet* are by some called the hands of a horse; but that term is in disuse, the common expression being the *fore-feet*, to denote the right *foot* before; and the *hind-feet*, to denote the left *foot* before.

Of the two hinder *feet*, the right is called the *far hinder-foot*; and when spurs were used, it was called the *spur-foot*, because in resting the spur, the socket of it answered the right hinder *foot*. The left hind *foot* is called the *near foot* behind.

Foot-dress, in the *Manège*. A horse's *foot* has this appellation when it is worn and waited by going without shoes, so that for want of a hoof, it is a hard matter to shoe him.

A horse's *foot* is said to be worn and waited, called in French *à pied*, when he has but little hoof, and not enough for shoeing.

Foot, is *gallop upon a good*, or put a horse upon a good *foot*, called in French *sur le bon pied*. See *Falle* GALLOP.

Foot, *fat*, in the *Manège*. A horse is said to have a *fat foot*, when the hoof is to thin and weak, that unless the nails be driven very short, he runs the risk of being pricked in shoeing. The English horses are very subject to this disorder.

Foot, in the *Military Art*, is used for *foot soldiers*, or the *infantry* of an army.

Foot, in the *Greek and Latin Poetry*, denotes a metre, or measure, composed of a certain number of long and short syllables.

The *spondee*, *iambic*, *trochee*, and *pyrrhic*, are dissyllabic *feet*; i. e. they consist of two syllables each; the *dactyl*, *anapest*, *molossus*, *tribrach*, *bacchius*, *ambichius*, *amphitrichus*, and *cereicus*, are trissyllabic, or consist of three syllables each; the *proceleusmaticus*, *chorambus*, and *epitrite*, are quadrissyllabic, or composed of four syllables. See each under its proper head, *Spondee*, *Iambic*, &c.

There are also other *feet*, invented by grammarians, of five, six, or more syllables; but they are not worth the naming.

Hexameter verses consist of six *feet*; *pentameters*, only of five.

Foot, *even and odd*, *par* and *impar*. In poetry, and particularly in *iambic verses*, *feet* are denominated *odd* and *even*, in respect of their situation in the verse. Thus, the first, third, and fifth, *feet* of the verse, are uneven; because these numbers are not capable of being divided into two equal parts.

In the ancient tragedy, the *iambic verses*, which prevailed therein, only allowed uneven *feet* to the spondee; so that the second, the fourth, and sixth *feet*, were to be *iambics*, because they were even. This regular mixture of spondee in the uneven *feet*, rendered the verse the more solemn and noble.

The comic poets, the better to disguise their verse, and make it more like prose, took the contrary course; putting spondee, where the tragic poets would only have allowed *iambics*.

Foot is also a long measure, consisting of twelve inches. The *foot* long is divided into twelve inches, and the inch into barley-corns.

Geometricians divide the *foot* into ten digits, and the digit into ten lines, &c.

The French divide their *foot*, as we do, into twelve inches; and the inch into twelve lines.

The *foot* square is the same measure, both in length and breadth, containing 144 square, or superficial inches.

The cubic, or solid *foot*, is the same measure in all the three dimensions, containing 1728 cubic inches.

The *foot* is of different lengths, in different countries. The Paris royal *foot* exceeds the English by nine lines and a half; the ancient Roman *foot* of the Capitol consisted of four palms, equal to eleven inches and four-tenths English; the Rhinland, or Leyden *foot*, by which the northern nations go, is to the Roman *foot*, as 950 to

1000. The proportions of the principal *feet* of several nations, compared with the English and French, are here subjoined.

The English *foot* being divided into one thousand parts, or into twelve inches, the other *feet* will be as follow:

	The Ft.	F. Inch.	Li.
London	Foot	1000	0 12 0
Paris <i>foot</i> , the royal, by Grævius	1068	1 0 9.7	
Paris <i>foot</i> , by Dr. Bernard	1066	1 0 1	
Paris <i>foot</i> , by Graham, from the measure of half the toise of the Châtelier, the toise containing six Paris feet	1065.417		
By Moanier, from the same data	1065.351		
From both these it may be fixed at	1065.4	1 0 9.4	
Amsterdam	Foot	942	0 11 3
Antwerp	Foot	946	0 11 2
Dort	Foot	1104	1 2 2
Rhinland, or Leyden	Foot	1033	1 0 4
Lerrain	Foot	958	0 11 4
Mechlin	Foot	919	0 11 0
Middleburgh	Foot	991	0 11 9
Strasbourg	Foot	920	0 11 0
Bremen	Foot	964	0 11 6
Cologne	Foot	974	0 11 4
Frankfort on the Mayn	Foot	948	0 11 4
Spanish	Foot	1001	0 11 0
Isiedo	Foot	809	0 10 7
Roman	Foot	967	0 11 6
Buonina	Foot	1204	1 3 4
Manica	Foot	1160	1 6 8
Venice	Foot	1162	1 1 9
Danzick	Foot	944	0 11 3
Copenhagen	Foot	965	0 11 6
Prague	Foot	1020	1 0 3

Old Roman	Foot	970	

Roman *foot*, from the monument of Constantine in Rome, by Grævius

From the monument of Statilius, by the same

Of Vespasian, deduced from the cognus of Vespasian

Mr. Roper, who has industriously collected a variety of authorities relating to the measure of the old Roman *foot*, determines the mean to be nearly 968 thousandths parts of the London *foot*. And by an examination of the ancient Roman buildings in Desgodet's *Edifices Antiques de Rome*, Paris, 1682, he concludes, that the Roman *foot* before the reign of Titus exceeded 970 parts in 1000 of the London *foot*; and in the reigns of Severus and Diocletian fell short of 965. Phil. Trans. vol. li. art. 69. p. 774. &c.

The Paris *foot* being supposed to contain 1440 parts, the rest will be as follow:

Paris	Foot	1440
Rhinland	Foot	1391
Roman	Foot	1320
London	Foot	1350
Swedish	Foot	1320
Danish	Foot	1403
Venetian	Foot	1540
Constantinopolitan	Foot	3120
Romanian	Foot	1682
Strasbourg	Foot	1282
Norimberg	Foot	1246
Danzick	Foot	1214
Hall	Foot	1320

In Scotland, this MEASURE of length, though consisting of twelve inches, exceeds the English *foot*, so that 185 of the former is equal to 186 of the latter.

Foot-hunt, or **Foot-slip**, in *Ferriquet*. See *BARQUETTE*.

Foot of the fersif, per fersif, in our *Ancient Customs*, contained 18 inches, or 15 of the common *foot*. *Natum est, quod per fersifem videretur tempore Ric. Orsill, in armentum vespertinum, fallus est, signatus & scriptus in parietis cancellis ecclesie de Edwinstre, & in cancellis Bate Mariae de Nottingham: Et distat per centum in longitudine octiduum palmis, &c. Ex Regill. Abb. de Novo Loco in Com. Not.*

Foot, fersif. See *Foot-fersif*.

Foot-skip was an ancient amusement, for cutting out the balls of the feet of great dogs in the forest; to prevent their running after the king's deer.

But about the measure of this sort of *force*, mathematicians are divided into two parties. Both sides agree, that the measure of this *force* depends partly upon the mass, or weight, of the body, and partly upon its velocity; so that upon any increase of weight or velocity, the moving *force* will become greater. It is also agreed, that the velocity being given, or being the same in two bodies, their *forces* will be in proportion to their masses or weights.

But when two bodies are equal, and the velocities with which they move are different, the two parties no longer agree about the measure of the moving *force*.

The Newtonians and Cartesians maintain, that the moving *force* is in proportion to the velocity with which the bodies move. But the Leibnizians assert, that the moving *force* is in proportion to the square of the velocity; so that if the velocity of a moving body be double, triple, quadruple, &c. of that of another equal body, the *force* of the former will be four times, nine times, sixteen times as great as that of the latter. See Dr. Jurin, in Phil. Trans. N^o 476.

Hence the Newtonians allege, that the momentum or moving *force* of bodies is in the compound ratio of their weights and velocities; and the Leibnizians, that it is in the compound ratio of their weights, and the squares of the velocities. If we allow the distinction, already stated, between the *vis viva* and the *vis inertia*, they appear, by the most familiar experiments with the balance, and other mechanical powers, to be in the simple proportion of the velocity multiplied into the mass: a four pound weight being placed at the distance of six inches from the centre of motion of a balance, and two pounds at the distance of twelve, will have a *vis viva*, if the balance be put into a swinging motion. These *forces* appear to be equal, because, with contrary directions, they soon destroy each other; but they are to one another in the simple ratio of the velocity multiplied into the mass, viz. $4 \times 6 = 24$, and $2 \times 12 = 24$. Whereas if the *forces*, in this case, had been as the mass into the square of the velocity, the weight 2 placed at near 8 1/2 inches would have destroyed the motion of the weight 4 at 6 inches distance, and have reduced it to an equilibrium; i. e. $4 \times 6 \times 4 = 144$; and $2 \times 12 \times 12 = 288$, &c. $\times 2 = 144$. With regard to the *vis inertia*, it is plain, that at the distance 12 keeps 4 in equilibrium at the distance 6; and the least alteration either of weights or distance, will destroy the equilibrium. Desag. Exp. Phil. vol. i. p. 393.

Though Leibnitz was the first that expressly asserted the *force* of a body in motion to be as the square of its velocity, in a paper inserted in the Leipzig Acts of the year 1686, yet Huygens has been thought to have led him into this notion, by some demonstrations in the fourth part of his book De Horologio Oscillatorio, relating to the centre of oscillation, and by his dissertations, in answer to the objections of the abbot Caztan, one of which was published in 1684. This eminent mathematician had demonstrated, that in the collisions of two bodies, perfectly elastic, the sum of the products of the bodies by the squares of their respective velocities, was the same after the shock as before; and this proposition is so far general as to obtain in all collisions of bodies that are perfectly elastic. It is also true, when bodies of a perfect elasticity strike any immovable obstacle, as well as when they strike one another; or when they are constrained by any power or resistance to move in directions different from those in which they impel one another. These considerations might have induced Huygens to lay it down as a general rule, that bodies constantly preserve their *specific force*, that is, the product of their mass, by the height to which their centre of gravity can ascend; and, therefore, in a given system of bodies the sum of the squares of their velocities will remain the same, and not be altered by the action of the bodies among themselves, nor against immovable obstacles. Leibnitz's metaphysical system led him to think that the same quantity of action or *force* subsisted in the universe, and finding this impossible, if *force* were destroyed by the friction of motion, he adopted Huygens's principle of the preservation of the *accidental force*, and made it the measure of moving *force*. But it also be observed, that Huygens's principle, above mentioned, is general only when bodies are perfectly elastic; and in some other cases, which Mr. Maclaurin has endeavored to distinguish, shewing as the same time that no useful conclusion in mechanics is affected by the dispute concerning the measurement of the *force* of bodies in motion, which have been objected to by mathematicians. Analyt. Query 9. See Maclaurin's Fluxions, vol. ii. art. 533. and preceding articles. *Hæc constantia est, corpora ferunt vim suam incommutem. & idcirco summum quadratum velocitatum illarum semper manere videtur. Hæc autem non solum tenet in ponderibus pendulorum & percussione corporum dura-*

rum, sed in multis quoque mechanis experimentis. Huygen, Oper. tom. i. p. 248.

Huygens, p. 247. of the same book observes, *Quod sepe perit *force* motus, hinc sunt in aliquo effectu aditus casusque, affirmare non possumus, ut in multis casibus percussione durorum corporum—ita ut minime pro lege naturæ inveniatur sit, eundem motum quantitatem semper conservari, nisi aliovi impudat & conservatur; sed hæc constantia lex est corpora ferunt vim suam incommutem.* &c. Where it is to be observed, that by hard bodies Huygens means such as are elastic, as appears from his treatise De Motu Corporum & Percussione, Oper. vol. ii.

But it is to be observed, that though it be true, that in the collision of elastic bodies the *vis viva*, or accidental *force*, is preserved before and after the shock; yet during the shock, while the elastic bodies are bending, and prels on each other, there seems to be a diminution of this *force*, which is afterwards restored by the action of their elasticity; though the followers of Leibnitz do not allow that any *force* is lost even during the shock. They say, the *vis viva* is communicated to the spring while it is bending, and then it is communicated to the bodies by the unbending of the spring. They also deny that any *force* is lost in the percussion of soft bodies. For though the *force* of the bodies impelling each other be diminished, yet their *force* does not perish, but is communicated to some other matter, such as the subtle fluid existing cohesion and elasticity. *Vis viva que in percussione vanitas, non perit sed convertitur.* Wolf. Confus. § 486.

In vis corporis semper conservatur, sedam circumstantiam quantitatem. Ibid. § 487. *Vis viva—dum figura corporum in contactu mutatur, in alia materia convertitur.* Ibid. Demonstr. § 486. Mr. Dan. Bernoulli, speaking of this principle of the preservation of the *vis viva*, observes, *Quamvis principium universale sit, non tamen est sine exceptione additionem, quæ sepe contingit ut materia transiret in materiam aliam.* *Ita enim præter solutissimum casum præ regulis motuum ex percussione corporum, si vis corpora sunt perfecte elastica; solutio non solum non perit, facile est videre, partem visum visum fieri auctorem potentiam in compressionem corporum in collisione corporum non resistit sed materiam visum visum, ut quoniam transiret, inveniuntur in hanc.* And Mr. Daniel Bernoulli, in this treatise, has assumed the preservation of the *vis viva* of Huygens, or, as others express it, the conservation of visum visum; and, in Mr. Bernoulli's own expression, *quantitas invariabilis absolute inquantumque potentiam*, as an hypothesis of wonderful use in mechanics. But a late author contents, that the conclusions drawn from this principle are often false than true. See De Conservat. Visum visum Differt. Lond. 1744. 4to.

Mr. Robins, in his remarks on Mr. J. Bernoulli's treatise, entitled, *Discours sur les Loix de la Communication de Mouvement*, informs us, that Leibnitz adopted this opinion through mistake; for, though he maintained that the quantity of *force* is always the same in the universe, he endeavours to expose the error of Des Cartes, who asserted, that the quantity of motion is always the same; and in his discourse on this subject in the Acts Eruditorum, 1686, he says, that it is agreed on by the Cartesians, and all other philosophers and mathematicians, that there is the same *force* requisite to raise a body of one pound to the height of four yards, as to raise a body of four pounds to the height of one yard; but being then how much he was mistaken in taking that for the common opinion, which would, if allowed, prove the *force* of the body to be as the square of the velocity it moved with, he afterwards, rather than own himself capable of such a mistake, endeavored to defend it as true; since he found it was the necessary consequence of what he had once asserted; and maintained, that the *force* of a body in motion was proportional to the height from which it must fall, to acquire that velocity; and the heights being as the squares of the velocities, the *force* would be as the masses multiplied by them; whereas, when a body descends by its gravity, or is projected perpendicularly upwards, its motion may be considered as the sum of the uniform and continual impulses of the power of gravity, during its falling in the former case, and till they extinguish it in the latter. Thus, when a body is projected upwards with a double velocity, these uniform impulses must be continued for a double time, in order to destroy the motion of the body; and hence it follows, that the body, by setting out with a double velocity, and ascending for a double time, must arise to a quadruple height, before its motion is exhausted. But this proves that a body with a double velocity moves with a double *force*, since it is produced or destroyed by the same uniform power continued for a double time, and not with a quadruple *force*, though it arises to a quadruple height; so that the error of Leibnitz consisted in his not considering the time, since the velocities

alone are not the causes of the spaces described, but the times and the velocities together: and yet this is the fallacious argument on which he first built his new doctrine; and those which have been since much insisted on, and derived from the indentings or hollows produced in soft bodies, by others falling into them, are much of the same kind. *Robins's Tracts*, vol. ii. p. 178. *Maclaurin's View of Sir I. Newton's Discov.* p. 135.

Catalan and Papin replied to Leibnitz's paper published in 1686; and from that time the controversy became more general, and was carried on for several years by Leibnitz, John and Daniel Bernoulli, Herman, Poleni, Wolfius, & Gravelande, Camus, Mufchenbroeck, &c. on one side; and Pemberton, Eames, Delaguerre, Dr. S. Clark, M. de Mairan, Jurin, Maclaurin, Robins, &c. on the other. See *Act. Acad. 1686, 1690, 1691, 1695, & Nouv. de la Rep. Let. Sept. 1686, 1687, art. 2. Comm. Epist. Inter Leibn. et Bern. Phil. vol. i. p. 393, &c. vol. ii. p. 49, &c. Robins, ubi sup.*

The nature and limits of this work will not admit our giving a full account of the arguments and experiments which have been repeatedly urged on both sides of this question. Those who are desirous of farther information than this article furnishes, with respect to the subject in dispute, may consult the preceding references. We shall, however, endeavour to collect a summary account of this controversy. The chief arguments that have been urged on both sides, have been deduced from the mutual collision of bodies, from the action of springs, from the composition and resolution of motion; from the impressions made by falling bodies on soft substances, and from some experiments in hydraulics relating to the velocities of fluids.

It is a well known law of motion, that action and reaction are equal with opposite directions, and are to be estimated always in the same right line; and from this law it follows, that the sum of the motions of any number of bodies, estimated in a given direction, continues the same in their mutual actions and collisions, till some external influence disturbs them. The advocates for the new opinion concerning the force of bodies have found it impossible to explain the actions and collisions of perfectly hard bodies, void of all elasticity, consistently with their doctrine; and, therefore, they have denied the existence of any such bodies; though it is reasonable to suppose, that the ultimate elementary particles of bodies, void of all pores, or atoms, are perfectly hard or inflexible, so as not to yield in the ordinary collisions of bodies; whilst they have admitted the existence of bodies perfectly elastic, none of which are to be met with in nature. Notwithstanding this evasion, they have been no less puzzled in explaining the collision of soft bodies, and reconciling the phenomena with their doctrine; for if a soft body with the velocity u , strikes another equal soft body, they will proceed as in one mass with the velocity $\frac{1}{2}u$, dividing the motion of the first body equally between them by the forementioned law. According to the new opinion, the force of the first body before the stroke was u , the force of each of them after the stroke is $\frac{1}{2}u$, and the sum of their forces after the stroke is $\frac{1}{2}u$; so that the sum of their forces after the stroke is only half of what it was before the stroke, while the quantity of motion is preserved the same as it was without any change. In order to account for the loss of one half of the force of the full body in the stroke, they allege, without proof, that when the parts of soft bodies yield without restoring themselves, being void of all elasticity, a certain quantity of force is lost in the compression of their parts by the collision; whereas there is no way by which force is lost in one body, but by the communication of it to another; so that there is no just reason for supposing, as they have done, that any motion or force is lost in flattening or hollowing soft bodies in their collisions.

If we admit the common rules of finding the velocities

of non-elastic bodies after collision, which Mr. Gravelande, an advocate for the new opinion, allows, it will follow, according to that opinion, that equal bodies may have unequal effects; e. g. let a and b be two equal non-elastic bodies; let b be at rest, while a moves towards it with eight degrees of velocity. In this case, the common velocity, after the stroke, will be half the velocity of a before the stroke, i. e. four degrees, dividing the sum of the quantities of motion in the two bodies by the sum of the quantities of matter; consequently the force in b , thus communicated by the stroke, will be as its square, or 16. Again, let b move forward with two degrees of velocity, and a follow it with ten degrees, the relative velocity will be 8 as before; and, therefore, the strokes in both cases are equal; the velocity of b after the stroke will be half the sum of the velocities before the stroke, or six degrees. According to the new opinion, the force being as the squares of the velocities, the force of a before the stroke will be to its force after the stroke, as the square of 8 is to the square of 6, i. e. as 4 to 36. Subtract the force of b before the stroke from the force it has after the stroke, and you have the degree of force communicated by the stroke, which, if this opinion be true, would be 32, i. e. double the number of degrees communicated by the same force in the former instance, which was 16; and, therefore, equal strokes produce unequal effects. The introduction of the parts, which is the other part of the entire effect of the stroke, will make but a small alteration in the matter; since the impressions in all cases are equal, when the relative velocity is supposed to be the same.

It has also been alleged by the advocates for the new doctrine, particularly by Mr. Bernoulli, that the preservation of the sum of the absolute motions of bodies, in their collisions, results immediately from the equality of action and reaction; the augmentation or diminution of the force of the one being the necessary consequence of the diminution or augmentation of the force of the other. But the third law of motion is general, and extends to bodies of all kinds; and it is well known that when soft bodies meet in opposite directions, the sum of their absolute motions or forces is diminished; and when the bodies are equal, and their velocities likewise equal, it is totally destroyed by this collision; and if two elastic bodies meet each other with contrary velocities, then on their first compression it is evident, that both their forces are diminished at the same time, and it may happen, that in restoring themselves, both their forces may be increased at the same time. It is not the sum of the absolute motions or forces of bodies, but this sum estimated in a given direction, that is preserved unaltered in their collisions, in consequence of the third law of motion; nor can the preservation of the sum of the absolute forces of any sort of bodies be considered as the immediate consequence of it.

The advocates for the new opinion further maintain, that the force of bodies is that power of acting in them, which must be measured by its whole effect, till its motion be destroyed; and they also lay it down as a definition or axiom, that force is proportioned to the number of springs which it can bend before it be consumed. Accordingly they shew, that a body with a velocity u , is able to bend and overcome the resistance of four springs, one of which alone is equivalent to the force of the same body moving with a velocity as 1; and hence they infer, that in the former case, the force is quadruple, though the velocity be only double of what it is in the latter case. But we may observe in general, that causes are not to be measured by any effects produced by them, considered without regard to their circumstances; thus, motions and forces are not to be measured by the effects produced, without regard to the times and directions of the motions. It is not considered in the preceding argument, and in others of a similar kind, that the force which one body loses, in acting upon another, is not equal to that which it produces or destroys in the other, estimated in any direction as pleasure, but in that only in which the first body acts; and that body, in consequence of its inertia, not only resists any change in its quantity of motion, but likewise any change in the direction of its motion. For the farther illustration of this argument, let the bodies A and B (*Tab. III. Motuum, Fig. 37.*) by moving towards each other, compress equal and similar springs placed between them till by the reaction of these springs their motions be destroyed. Mr. Bernoulli expressly owns, that the actions of the springs of these bodies are constantly equal to each other; and yet maintains that they destroy a force in B greater than the force of A , in the same proportion as the body A is greater than B , or (C being the centre of gravity of A and B) as CB is greater than CA . He, therefore, maintains that equal pressures or actions of springs generate, in the same time,

press that may be unequal in any assignable ratio, which is repugnant to the plainest notions we can form of action and force. If we suppose the body A to compress the springs from A to C, then the body B will compress all the springs from C to E, in the same degree, and in the same time; and thence he infers, that the force of A is to the force of B in the same proportion as the number of springs from C to A to the number of springs from C to E. But since the motion, force, or effect of any kind, produced or destroyed in A or B, depends upon the immediate action which produces the effect, and upon it only; and since, in this case, the actions of the springs upon the bodies A and B are those which destroy their motion; and since it is allowed that the actions of the springs on these bodies are equal, it is not evident that the forces destroyed by them in the same time must be equal? And is it not manifest, that the forces which are produced or destroyed in bodies are to be measured by the efforts which the springs exert upon the bodies in producing this effect, and not by the number of springs? It is the last spring only which is in contact with the body that acts upon it, the rest serving only to sustain it in its action, and, therefore, any change produced in the body, by whatever name it be called, ought to be determined from the action of this last spring only, and in fact reasoning ought to be computed from this alone. Moreover, if two unequal bodies, moving with unequal velocities, strike upon two equal springs, with one end hinged against an immovable support, and each of them bend the spring on which it strikes exactly to the same degree; and in so doing the moving force of each body be entirely consumed; in this case there will be, according to the Leibnizians, two equal effects produced, since the springs are equal, and equally bent, and the moving forces are wholly consumed in producing them; and, therefore, on their principles, these moving forces, being the causes of equal effects, must be equal. But those who espouse the old opinion, deny this conclusion, unless the times of producing these effects are equal; and they allege in the present case that the greater body will take up a longer time in producing its effect, or in bending its spring; consequently the moving forces of these two bodies may be unequal, though they bend equal springs to the same degree. In like manner, when a spring, already bent to some certain degree, does, by unbending, drive before it a body which gave way to its pressure, the pressure of the spring may produce a greater effect, when it continues for a longer time. Dr. Jurin has very accurately considered the action of springs. Having premised the three following axioms, viz. 1. That a spring will unbend itself more slowly according to the size of the body against which it acts; 2. That its pressure is according to the degree in which it is bent; and, 3. That a greater pressure produces a greater moving force in a given time: he deduces from them the following proposition, viz. the moving forces are not proportional to the masses of the bodies, and the squares of their velocities; for when two springs, A and B, equal, and equally bent, pass before them by unbending two unequal bodies, the spring A, which acts on the greater body, will unbend more slowly than the other, and, therefore, in every instant of time, will have unbent itself less than B; consequently its pressure will be greater than that of B at the same instant; and the infinitely small moving force produced by A in every moment will be greater than that of B; whence it follows, that the sum of the infinitely small moving forces, i.e. the whole moving force, produced by A, will be greater than that of B in the same time; so that the spring A, not being wholly unbent, when the pressure of B ceases, will continue to act on the greater body, the moving force of which will increase, and, therefore, more and more exceed the moving force of the smaller body; but, since the products of the masses and squares of the velocities are equal in the two bodies, the moving forces, which are proved to be unequal, cannot be proportional to the same products. He then subjoins the two following axioms, viz. 4. That springs of unequal lengths, when bent alike, have equal pressures; and, 5. That equal pressures in equal times produce equal moving forces; from which he deduces his second proposition, that moving forces are proportional to the masses and velocities jointly. Thus, if there be two springs, of the lengths 1 and 2, but equal in all other respects, and bent alike; and the spring 1, in unbending itself, be made to drive before it a body whose mass is 2, and the spring 2 another body of the mass 1, these two springs, by what he has elsewhere demonstrated, will unbend themselves exactly in the same time; and, therefore, the spring 2 will unbend itself with a velocity double of that of the spring 1; and it will give to the body 1 a velocity double of that, which the body 2 will receive from the spring

1; consequently, the two springs, during the whole time of their expansion, will be always bent alike; and, by axiom 4, their pressures will be constantly equal; and by axiom 5, the infinitely small moving forces produced by each of these springs, in every infinitely small part of time, will be equal one to the other; therefore, the sums of these infinitely small moving forces, i.e. the whole moving forces, produced by the two springs, will be equal. And as the masses of the two bodies are 2 and 1, and their velocities 1 and 2 respectively, the moving forces must be proportional to the masses and velocities jointly. From these principles, Dr. Jurin infers, that the Leibnizian opinion about the measure of moving force is incontestably overturned by the first proposition, and the opposite opinion evidently established by the second.

It is a well known theorem in mechanics, that the motions and actions of bodies upon each other, in a space that is carried uniformly forward, are the same as if that space were at rest; and any powers or motions that act upon all the bodies, so as to produce equal velocities in them in the same or in parallel right lines, have no effect on their mutual actions or relative motions. From this theorem, Mr. Maclaurin has deduced the following argument against the new doctrine concerning the forces of bodies in motion. Let A and B (Tab. III. *Mechanica*, fig. 38) be two equal bodies that are separated from each other by springs interposed between them in a space E, F, G, H, which in the mean time proceeds uniformly in the direction BA, in which line the springs act, with a velocity as 1; and let the springs impress on the equal bodies A and B equal velocities, in opposite directions, that are each as 1. Then the absolute velocity of A, which was as 1, will be now as 2; and, according to the new doctrine, its force as 4; whereas the absolute velocity, and the force of B, which was as 1, will be now destroyed; so that the action of the spring adds to A a force as 3, and subtracts from the equal body B a force as 1 only; and yet it seems manifest that the actions of the springs on these equal bodies, ought to be equal; which Mr. Bernoulli allows; i.e. equal actions of the same springs on equal bodies would produce very unequal effects, the one being triple of the other according to the new doctrine, than which hardly any thing more absurd can be advanced in philosophy or mechanics. In general, if m represent the velocity of the space E, F, G, H, in the direction BA, n the velocity added to that of A, and subtracted from that of B, by the action of the springs, then the absolute velocities of A and B will be represented by $m+n$ and $m-n$ respectively, the force added to A by the springs will be $2mn+nn$, and the force taken from B will be $2mn-nn$, which differ by $2nn$. Further it is allowed that the actions of bodies upon one another are the same in a space proceeding with an uniform motion as if the space was at rest; but if the space E, F, G, H, was at rest, it is allowed, that the forces communicated by the springs to A and B had been equal; and, by the new doctrine, the force of each had been represented by nn ; whereas the force communicated to A by the springs in the space E, F, G, H, is represented by $2mn+nn$, and the force taken from B will be $2mn-nn$.

It has been further urged by the advocates for the new opinion, that, since a body moving with a velocity proportional to the diagonal of a rectangle is able to balance the resistance of two springs proportional to the sides of the same rectangle, the force of a body moving with a velocity, as the diagonal, is equal to the sum of the forces of two bodies moving with velocities proportional to the sides of the rectangle; and, because the square of the diagonal is equal to the sum of the squares of the two sides, they thence infer, that the forces of equal bodies are as the squares of their velocities. Mr. Maclaurin has very largely discussed this argument, and shewn that it contradicts not only their own principles but the established laws of motion. It is well known to those who are acquainted with the composition and resolution of motion, that powers acting in the directions AB and AD (Tab. III. *Mechanica*, fig. 39) proportional to those right lines, compound a power acting in the direction of the diagonal AC, and measured by it; and this compound power must be less than the sum of the simple powers, because AC is less than AB+AD. This is easily accounted for by resolving the power AB into AM and AN, and the power AD into AK and AL, of which AN and AL are opposite and equal, and destroy each other's effect, so that there remains AM+AK or AC, the measure of the compounded power. The followers of Leibnitz agree in this manner of arguing concerning powers and pressures, but not in the composition and resolution of forces; for, according to them, when the angle BAD is right, the compounded force is equal

equal to the sum of the *forces* AB and AD, and no *force* is lost, notwithstanding the opposite directions of the *forces* AL and AN. When the angle BAD (fig. 43) is acute, the square of the diagonal AC exceeds the sum of the squares of AD and DC, or of AD and AB; and therefore the two *forces* in the directions AD and AB must, according to the new doctrine, compound a *force* AC greater than their sum; a consequence which contradicts their own metaphysical principle, that the effect is proportional to the cause which produces it, because the effect is, in this case, greater than the cause, and is as absurd in mechanics, as that two quantities collected together should produce a greater quantity than their sum in geometry; whereas, it appears from a view of the figure, that AL and AN, parts of AD and AB, destroy each other; and, therefore, the whole *force* AD and AB are not accumulated in the direction AC, but only their parts AM and AN, which when taken together are equal to AC, because the triangles ADK and BMC are similar and equal; so that the *force* in the direction AB and AD compound a *force* in the direction AC less than their sum, whilst the square of AB and AD, taken together, exceed the square of AC; consequently the *forces* are not to be measured by the square of the lines. Further, let the elastic body A (fig. 44) exercise its *force* in the direction AB, from the equal elastic body H, and its *force* in the direction AD, from the equal elastic body G, at the same time. According to the notions of the new doctrine the *forces* of H and G are communicated to A by infinitely small degrees, or by an uninterrupted succession of pressures, and the whole *force* communicated to A is the sum of the effects of these pressures. Now in every instant, the pressure, or infinitely small *force* impressed on A, is less than the sum of the pressures exerted in that instant by H and G, in proportion as AC is less than AB+AD, as is allowed on all sides. Therefore the sum of all the pressures, or the *force* impressed on A, must be less than the sum of all the pressures, or the sum of the *forces* exerted by H and G, in the same proportion of AC to AB+AD; that is, the *force* of A, H and G, must be as the lines AC, AB, and AD, and not as their squares. It is not possible to conceive, that while the *force* in A arises from the accumulation of the pressures, or infinitely small *forces*, which it receives every moment from the actions of H and G, and each of these pressures, or infinitely small *forces*, is less than the sum of the actions of H and G that produce them; yet the whole *force* of A should, nevertheless, exceed the sum of the whole actions or *forces* of H and G. If the angle BAD be infinitely acute, the same *force* (according to the new opinion) generate a *force* in A, which exceeds their sum as much as the figure of AB+AD exceeds the sum of the squares of AB and AD; so that if AD be equal to AB, they will in that case generate at A a *force* double of their sum, for then the square of AB+AD will be equal to the square of 2 AB = 4 AB²; though the two equal *forces* which are supposed to produce this, taken together, amount only to 2 AB², according to their own computation; and, therefore, in this case, a cause produces an effect of the same kind double of itself.

In the resolution of motion, motion is gained; and as the powers that generate motion are increased, the effects of these powers, or the *forces* of bodies, must be increased likewise. Mr. MacLaurin has illustrated and applied this principle in the following manner. Let the body C (fig. 42.) moving in the direction DC, the diagonal of the parallelogram, CLDK, strike the equal body A obliquely, so as to impel it in the direction CA, the continuation of CK, and at the same time the equal body B, in the direction CB, the continuation of CL; the body A will proceed in the right line CA, and the body B will proceed in the direction CB, the continuation of CL, and C having communicated all its *force* to them, will stop. It will not appear strange, that the motions and *forces* of A and B exceed the motion or *force* of C, if we consider that C communicates the whole motion or *force* CK to A, and the whole motion or *force* CL to B, that the resistance or inertia of A resting upon C, not in the direction of its motion CD, but in the direction CK, oblique to it, the absolute motion or *force* of C, in the direction of DC, is not so much diminished by this reaction as if it was directly opposite to the motion of C; for no power or resistance can produce so great an effect in any direction as in that wherein it acts. In like manner, the reaction of B destroys the *force* LC in the body C, in the direction in which B reacts; but not to great a motion or *force* in the direction DC, to which it is oblique; and thus it appears, that the motion or *force* of C, in the direction DC, must necessarily be less than the sum of the motions or *forces* of the bodies A and B in their respective directions. It may also be

observed, that in consequence of the inertia of body, it not only resists any change of its motion, but likewise any change in the direction of its motion; and when the action of bodies upon each other is not in a right line, both these are to be taken into the account. Thus, if C strike A, the reaction of A has a twofold effect; it subduces somewhat from the motion or *force* of C, and produces a change in its direction; and its whole reaction is to be eliminated by both these effects conjointly. After the body C has struck A, it proceeds in the right line CL with a motion or *force* as CL, and impinging on B directly, it communicates its whole motion or *force* to B, which reacts directly against it; the bodies C, A, and B, are supposed to be perfectly elastic. If springs be substituted, instead of the bodies A and B, and their resistances measured by CK and CL, the resistances of those springs are not the proper measures of the *force* of the body C, but taken together, they must exceed it; because the spring A acts as a disadvantage against the motion or *force* of C. It has its whole effect in the direction CK, in which it reacts; but not to great an effect in the direction CD, oblique to that in which it acts. If the spring A acted with the same advantage as B, they would together produce a greater effect than in the situation they have in the figure; and, therefore, the greatest resistances which they are able to exert taken together, must exceed the *force* of the body C. Thus, says Mr. MacLaurin, it appears, that this argument, instead of overthrowing the old doctrine, confirms it, and that they who advanced it supposed these *forces* to be equal, which, according to the known principles of mechanics, are unequal. In other instances, the followers of N. Leibnitz neglect the consideration of time, in reasoning concerning the *force* of bodies; in this case they do not duly regard the directions of motions and *forces*, in estimating and comparing their effects. Mr. Lamez has likewise shown, that the argument drawn from the compulsion and resolution of *force*, equally proves both sides of the question, and by thus proving too much, proves nothing. Another argument advanced in favour of the new opinion, has been founded on the learned and ingenious Mr. Poleni's experiment, in which equal cavities are formed in soft substances, by equal bodies falling from heights reciprocally proportional to their masses; whence it has been inferred, that the bodies strike with equal *force*, and, therefore, that the *force* of the same body in descending is proportional, according to Mr. Leibnitz's principle, to the height from which it falls, or, in all motion, proportional to the square of the velocity. Dr. Jurin has set this argument aside, as insufficient, since the times of forming these equal cavities are unequal and unequal causes may produce equal effects in unequal times. Mr. Poleni, indeed, maintains, that the formation of these cavities seems to be instantaneous; but Dr. Jurin has shewn the contrary, even from a position allowed by Poleni himself. Dr. Pemberton asserts and proves, that this experiment of Poleni is not only reconcilable to the common doctrine of motion, but that it manifests the great unreasonableness, if not the absolute absurdity, of Mr. Leibnitz's opinion; and Dr. Deaguliers observes, that Poleni's mistake lies in this; that he estimates the *force* of the stroke of the falling balls, by the depth of the impression made in the yielding substance; but this is not the whole effect; for when two bodies move with equal *force*, but different velocities, that which moves the fastest must make the deepest impression; whilst the slowest body communicates its motion to the substances round about, and, therefore, does not sink in so deep as the faster body, which puts in motion few parts of the clay, besides those that are before it, and which have so much less time to oppose this body's motion, as its velocity is greater.

The ingenious Mr. Graham, in confirmation of the old opinion, prepared a pendulous body, with a cavity in it, capable of receiving another body of an equal weight, at the lowest point of its vibration; and when the body was dropped into it, he found, by the subsequent vibration, that the velocity of the double mass was precisely one half of the velocity of the pendulum before; from which it appears, that the same *force* produces in a double quantity of matter one half of the velocity only; which is agreeable to the common doctrine, but directly repugnant to the new one, concerning the *force* of bodies in motion.

The advocates for the new opinion have produced in favour of it some experiments in hydraulics, the result of which is, that the velocities of any fluid, issuing out at equal orifices made in the sides of vessels filled up to different heights, and kept full at those heights, above the orifices, are found to be as the square roots of those heights respectively; whence they infer, that the *forces* of equal masses, or moving bodies, are proportional to the

the squares of their velocities. Every single particle, they say, issuing out with two degrees of velocity, must move with four times the force of any other single particle that moves with only one degree of velocity; because the force with which it moves is the effect of a cause four times greater, or the pressure of a column of water four times higher, &c. The pressures are as the altitudes, and the altitudes as the squares of the velocities of every single particle; therefore the pressures are as the squares of the velocities; but the pressures being the causes of the forces, with which the several particles issue out or move, and effects being proportional to their causes, the forces must be as the squares of the velocities. On this reasoning, Mr. Eames has remarked, that the entire effect of any of these pressures is not barely a certain number of degrees of velocity, in any single particle, but certain degrees of velocity in a certain number of particles, which number of particles, in a given time, is, confessedly, as the degrees of velocity. Besides, it is acknowledged, that the quantities of the fluid, pressed out in equal times, are as the velocities. See *Gravæ. Epit. Elem. Phys. Math.* part II. cap. 4. p. 655.

If this be true, the forces cannot be as the quantities of matter multiplied by the squares of the velocities; for then the effects would be more than in proportion to their causes. E. g. the effect of a pressure of a column of water, nine inches high, instead of being nine times greater than that of one inch above the orifice, would be no less than twenty-seven times greater; for the velocity being at this height triple, the quantity of matter, in a given time, will be also triple; which multiplied by the square of the velocity gives 27 for the force communicated by a pressure of 9 inches in altitude, while the force communicated by the pressure of 1 inch, is but as 1; so that the moving force produced will be as 27 to 1, while the causes producing these forces are but as 9 to 1, i. e. three times too little for such a purpose. In reality the common rule of estimating the force of moving bodies by the quantities of matter multiplied by their velocities, is confirmed by these experiments; for, effects being proportional to their causes, the forces communicated will be as the forces communicating, or pressures. Thus, let the altitude and consequent pressure of any column of water, be nine times greater than the altitude of another; then the velocity of every single particle of water pressed out will be triple, and the number of particles issuing out in a given time will likewise be triple; therefore, the force resulting from these 2, multiplied together, according to the common rule, will be 9, proportional to the pressure, as it ought to be, &c. And universally, the forces communicated, according to the old rule, are in a ratio compounded of two others, viz. the quantities of matter and the velocities; the ratio of the velocities, by the experiments, is the subduplicate ratio of the heights, and the ratio of the quantities of matter is, confessedly, likewise the subduplicate of the heights; therefore the compound of these two is the ratio integer, or simple ratio of the heights, in which ratio are the pressures themselves, which produce their moving forces; so that, according to the common rule, the effects are always proportional to their causes. After this manner professor Grævesande reasons in page 355. of his *Phys. El. Math.* ed. 1.

Many of the experiments and reasonings, that have been urged on both sides in this controversy, have been founded in the different senses applied to the term force. The English and French philosophers mean by the word force the same thing as they do by momentum, motion, quantity of motion, or instantaneous pressure, which is measured by the mass multiplied into the velocity, and may be known by its effect; and when they consider bodies as moving through a certain space, they allow for the time in which that space is described; whereas the Dutch, Italian, and German philosophers, who have espoused the new opinion, mean by the word force, or force inherent in a body in motion, that which it is able to produce; or, in other words, the force is always measured by the whole effect produced by the body in motion, until its whole force be entirely communicated or destroyed, without any regard to the time employed in producing this total effect. Thus, say they, if a point runs through a determinate space, and presses with a certain given force or intensity of pressure, it will perform the same action whether it move fast or slow, and therefore the time of the action in this case ought not to be regarded. *Grævesande, lib. cit. p. 233-238.*

Lobnitz himself assumed it as certain, that the action is as the effect by the velocity with which it is produced; and hence he deduces, that the power is as the mass by the square of the velocity: his words, as quoted by Wolfius, are, *Calculus visum præterea seu aliquid tale infusus. Sit spatium s , tempus t , velocitas v , corpus c , ef-*

fectus e , potentia p , actio a , in motu æquabili erit in s , t , v , c , e ut s , t , v ut a . Atque hæc quidem sine demonstratione æstimate possunt. Accedit quod demonstrandum, e ut a . Hæc præterea plurimum thetæmaticè demonstrari possunt, e ut p , p ut a . Nam p ut a ut c : sed e ut c ut v ut v . Ergo e ut v ut v ut v , e ut v , e ut v . Vide Act. Philosoph. tom. II. p. 238.

Mr. Euler observes, with respect to this dispute concerning the measure of vital force, that we cannot absolutely ascribe any force to a body in motion, whether we suppose this force proportional to the velocity, or to the square of the velocity; for the force exerted by a body, striking another at rest, is different from that which it exerts in striking the same body in motion; so that this force cannot be ascribed to any body considered in itself, but only relatively to the other bodies it meets with. There is no force in a body, absolutely considered, but its inertia, which is always the same, whether the body be at rest or in motion. But if this body be forced by others to change its state, its inertia then exerts itself as a force, properly so called, which is not absolutely determinable; because it depends on the changes that happen in the state of the body. Suppose, for instance, a body A forced to move in an inviscid tube, or along the curve surface E A F (*Tab. Mechanica, fig. 43.*) the body in this case will press the surface wherever it touches it in a direction a normal to the curve; and with a certain force commonly determined in mechanics, by the mass of the body, its velocity, and by the radius of curvature O A. Now the body exerts a pressure, or vis mortua; yet it would be absurd to ascribe a certain and determinate force of pressure to this body considered in itself, since this pressure may vary very much, according to the difference of the curvature of E A F. In like manner, it seems unreasonable to place a certain absolute force of percussion in bodies, since it principally depends on the external circumstances accompanying the shock.

A second observation which has been made by several great men, is, that the effect of a shock of two or more bodies is not produced in an instant, but requires a certain interval of time. If this be so, the heterogeneity between the vis viva and vis mortua vanishes; since a pressure may always be assigned, which in the same time, however little, shall produce the same effect. If then the vis viva be homogeneous to the vis mortua, and since we have a perfect measure and knowledge of the latter, we need require no other measure of the former than that which is derived from the vis mortua equivalent to them.

Now that the change of the state in the shock of two bodies does not happen in an instant, appears evidently from the experiments made on soft bodies: in these, percussion forms a small cavity, visible after the shock, if the bodies have no elasticity. Such a cavity cannot certainly be made in an instant. And if the shock of soft bodies require a determinate time, we must certainly say as much of the hardest, though this time may be so small as to be beyond all our ideas. Neither can any instantaneous shock agree with that constant law of nature, by virtue of which nothing is performed per saltum. But it is needless to insist farther on this, since the duration of any shock may be determined from the most certain principles.

There can be no shock or collision of bodies, without their making mutual impressions on each other: these impressions will be greater or less, according as the bodies are more or less soft, other circumstances being the same. In bodies called hard, the impressions are small; but a perfect hardness, which admits of no impression, seems inconsistent with the laws of nature; so that while the collision lasts, the action of bodies is the result of their mutually pressing each other. This pressure changes their state; and the force exerted in percussion are really pressures, and truly vis mortua, if we will use this expression, which is no longer proper, since the pretended infinite difference between the vis viva and vis mortua ceases. See *HARDNESS*.

The force of percussion, resulting from the pressures bodies exert on each other while the collision lasts, may be perfectly known, if these pressures be determined for every instant of the shock.

The mutual action of the bodies begins the first moment of their contact, and is then less; after which this action increases, and becomes greatest when the reciprocal impressions are strongest. If the bodies have no elasticity, and the impressions they have received remain, the force will then cease. But if the bodies be elastic, and the parts compressed restore themselves to their former state, then will the bodies continue to press each other till they separate. To comprehend therefore perfectly the force of percussion, it is requisite to define, first, the time the shock lasts, and then to assign the pressure corresponding

responding to each instant of this time; and as the effect of pressures in changing the state of any body may be known, we may thence come at the true cause of the change of motion arising from collision. The force of percussion, therefore, is no more than the operation of a variable pressure during a given time; and to measure this force we must have regard to the time, and to the variations according to which the pressure increases and decreases.

Mr. Euler has given us some calculations with respect to these particulars. It will be sufficient here only to illustrate their tendency by the instance he brings. Suppose two bodies A and B; that the hardness of these bodies is equal; and such, that being pressed together with the force of 100 lb. the impression made on each is of the depth of $\frac{1}{4}$ of a foot. Suppose, further, B to be at rest, and fixed, and that A strikes it with the velocity of a 100 feet in a second; according to Mr. Euler, the greatest force of compression will be equivalent to 4000 lb. and this force will produce in each of these bodies an impression equal to $\frac{1}{4}$ of a foot, and the duration of the collision, that is, till the bodies arrive at their greatest compression, will be about $\frac{1}{20}$ of a second. Mr. Euler, in his calculations, supposes the hardness of a body to be proportional to the force or pressure requisite to make a given impression on it; so that the force by which a given impression is made on a body, is in a compound ratio of the hardness of the body and of the quantity of the impression. But he observes, that regard must be had to the magnitude of the bodies, as the same impression cannot be made on the least bodies as on the greatest, from the defect of force through which their component particles must be driven; he, therefore, only considers the least impressions, and that the bodies are of such magnitudes, that with respect to them the impressions may be looked upon as nothing. What he supposes about the hardness of bodies, neither implies elasticity nor its defect, elasticity only producing a restitution of figure and impression when the pressing force ceases; but this restitution needs not be here considered. It is likewise supposed, that the bodies striking each other have plane and equal bases, by which they touch each other in the collision; so that the impression hereby made diminishes the length of each body. It is farther to be observed, that in Mr. Euler's calculations, bodies are supposed to continue, that they may not only receive impressions from the forces pressing them, but that a greater force is requisite to make a greater impression. This excludes all bodies fluid or solid, in which the same force may penetrate farther and farther, providing it have time, without ever being in equilibrium with the resistance. Thus a body may continually penetrate farther into soft wax, although the force impelling it be not increased. In these, and the like cases, nothing is required but to surmount the first obstacles; which being once done, and the connection of parts broken, the penetrating body always advances, meeting with the same obstacles as before, and destroying them by an equal force. But Mr. Euler only considers the first obstacles which exist before any separation of parts, and which are, no doubt, such, that a greater impression requires a greater force. This, indeed, principally takes place in elastic bodies; but it seems likewise to obtain in all bodies when the impressions made on them are small, and the texture of their parts is not altered.

These things being premised, let the mass or weight of the body A be expressed in general by A, and let its velocity before the shock be that which it might acquire by falling from the height a . Further, let the hardness of A be expressed by M, and that of B by N, and let the amplitude of the base by which the impression is made, be cc ; then will the greatest compression be made with

a force $\sqrt{\frac{M \times N}{M + N}} \times A \times a$. Therefore if the hardness of

the two bodies, and the plane of their contact during the whole time of their collision be the same, this force will be $\sqrt{A \times a}$, that is, as the square root of the *vis viva* of the striking body A. And as $\sqrt{A \times a}$ is proportional to the velocity of the body A, the force of percussion will be in a compound ratio of the velocity and of the subduplicate ratio of the mass of the body striking; so that in this case neither the Leibnizian nor the Cartesian proportions take place. But this force of percussion depends chiefly on the hardness of the bodies, the greater this is, the greater will the force of percussion be. If $M=N$, this force will be as $\sqrt{M \times N \times A \times a}$, that is, in a compound subduplicate ratio of the *vis viva* of the body striking, of the hardness, and of the plane of contact. But if M, the hardness of one of the bodies, be infinite, the force of percussion will be as $\sqrt{N \times A \times a}$; at the same time, if $M=N$, this force will be as $\sqrt{N \times A \times a}$. There-

fore all other things being equal, the force of percussion? if the striking body be infinitely hard, will be to the force of percussion, if both the bodies be equally hard, as $\sqrt{a}$ to 1. Mr. Euler farther deduces from his calculations, that the impression received by the body A will be as

$\sqrt{\frac{N \times A \times a}{M + N \times M}}$, and the impression on B will be as $\sqrt{\frac{M \times A \times a}{M + N \times M}}$. If, therefore, the hardness of A,

that is M, be infinite, it will suffer no impression, whereas that on B will extend to the depth of $\sqrt{\frac{A \times a}{N}}$. But

if the hardness of the two bodies be the same, or $M=N$, they will each receive equal impressions of the depth $\sqrt{\frac{A \times a}{2N}}$. So that the impression received by the body B, in this case, will be to the impression it receives in the former as 1 to $\sqrt{2}$.

Mr. Euler has likewise considered and computed the case when the striking body has its anterior surface convex, with which it strikes an immovable body whose surface is plane. He has also examined the case when both bodies are supposed immovable; and from his formulae he deduces the known laws of the collision of inelastic and elastic bodies. He has also determined the greatest pressures the bodies receive in these cases; and likewise the impressions made on them. In particular he shews, that the impression received by the body struck, or B, if movable, is to the impression received by the same body when immovable as $\sqrt{B}$ to $\sqrt{A+B}$.

The doctrine of Mr. Euler may serve to shew, that the dispute about the measure of force is very needless in physics; since the laws of motion may, independently of any hypothesis about the measure of the *vis viva*, be deduced from the most uncontested principles of pressure and time. But we doubt whether we shall be enabled hereby to settle the metaphysical part of this dispute to the satisfaction of both parties, each of which may assert to all that Mr. Euler says, and yet adhere either to the Cartesian or Leibnizian. But whatever may be said of the metaphysical part of the dispute, it is certain, from experience,

That the number of equal springs requisite to produce any velocity in a given body, is always proportional to the square of the velocity to be produced. Thus if one spring can, by unbending half, produce one degree of velocity in a body, it will require four equal springs to produce two degrees of velocity in that body, nine springs to produce three degrees of velocity, &c. See SPRING. Also, if a portion of a yielding substance, as clay, tallow, &c. be just sufficient to stop the motion of a body moving with a certain degree of velocity, it will require four times the quantity of the same yielding substance to stop it, if the velocity of the moving body be double, &c. The same holds in the resistance of wood against mail-quills, as Mr. Robins observes in his New Principles of Gunnery; so that a ball moving with twice the velocity of another, will penetrate four times as deep into earth, clay, tallow, wood, &c. And in the manner if the action of one man, one horse, or other animal, can give a certain degree of velocity to a given mass, it will require the action of four equal men, horses, &c. to give the same mass two degrees of velocity; nine men, horses, &c. to give it three degrees of velocity; and so on.

These practical points have been put out of all question by the experiments of Poloni, *Guevande, Desaguliers, and others, and are of great use, although they do not decide the controversy about the measure of the force of bodies in motion.

FORCE, accelerating. See *Via aspiratrix*, and ACCELERATION.

FORCE, attractive. See ATTRACTION.

FORCE, central. See CENTRAL.

FORCE, centrifugal. See CENTRIFUGAL.

FORCE, centripetal. See CENTRIPETAL.

FORCE of cohesion. See COHESION.

FORCE, contractile. See CONTRACTILE.

FORCE, elastic. See ELASTIC, and ELASTICITY.

FORCE, electrical. See ELECTRICITY.

FORCE of gravity. See GRAVITY.

FORCE of the heart. See HEART.

FORCE of insensibility. See *Via insensibilis*.

FORCE, innate. See *Via insita*.

FORCE, magnetic. See MAGNETISM.

FORCE, moving. See *Via motus*, and preceding article, FORCE.

FORCE, repelling. See REPELUSION.

FORCE, resisting. See RESISTANCE.

FORCE, retarding. See RETARDATION.

FORCE of wind. See WIND, &c.

FORCE, in *Common Law*, signifies an offence, by which violence is used either to persons, or things.

Force is either *simple*, or *compound*.

Force, mixed, or *compound*, is violence committed with some felony, which of itself alone were criminal: as if any man by *force* enter into another man's possession, and there kill a man, or ravish a woman, &c.

Force, simple, is that which has no other crime adjoined to it: if one, by *force*, enter into another man's possession, without doing any other unlawful act.

Force is also divided into *free force*, or *force after a writ*.

There are other branches, as *forcible entries, forcible detentions*, or holding unlawful assembly, riots, rebellions, &c.

Force, frigid. See *FRESH*.

FORCE, in *Grammar*, and some other arts, is applied to a thing which stands in lieu of, or has the same effect, as another. In our language, the *f* between two vowels has the *force* or power of a *u*, and is sometimes put for a *u*, as in *horridum, baptizing*, &c.

In Hebrew, the *dagesh* and in Arabic, the *tafsid*, have the *force* of a letter suppressed. An *enir* before a cypher, has the *force* of ten.

FORCE, in *practical Mechanics*. We have several chious as well as useful observations in Desaguliers's *Experimental Philosophy*, concerning the comparative *force* of men and horses and the best way of applying them. A horse draws with the greatest advantage when the line of direction is level with his breast: in such a situation, he is able to draw 200 lb. eight hours a day, walking about two miles and an half an hour. And if the same horse is made to draw 240 lb. he can work but six hours a day, and cannot go quite so fast. On a carriage, indeed, where friction alone is to be overcome, a minding horse will draw 1000 lb. But the best way to try a horse's *force*, is by making him draw up out of a well, over a single pulley or roller; and in such a case, one horse with another will draw 200 lb. as already observed.

Five men are found to be equal in strength to one horse, and can, with as much ease, push round the horizontal beam of a mill, in a walk forty feet wide; whereas three men will do it in a walk only nineteen feet wide.

The worst way of applying the *force* of a horse, is to make him carry or draw up hill: for, if the hill be steep, three men will do more than a horse, each man climbing up faster with a burden of 100 lb. weight, than a horse that is loaded with 300 lb. a difference which is owing to the position of the parts of the human body being better adapted to climb than those of a horse.

On the other hand, the best way of applying the *force* of a horse, is an horizontal direction, wherein a man can exert least *force*. Thus a man, weighing 140 lb. and drawing a boat along, by means of a rope coming over his shoulders, cannot draw above 27 lb. or exert above one seventh part of the *force* of a horse employed to the same purpose.

The very best and most efficient posture in a man, is that of rowing; wherein he not only acts with more muscles at once for overcoming the resistance, than in any other position; but as he pulls backwards, the weight of his body assists by way of lever. Desaguliers, *Exp. Phil.* vol. i. p. 241. where we have several other observations relative to *force* acquired by certain positions of the body, from which that author accounts for most feats of strength and activity. See also a *Memoire* on this subject by M. de la Hire, in *Mem. Roy. Acad. Sc.* 1629; or in Desaguliers, *Exp. &c.* p. 267. &c. who has published a translation of part of it with remarks.

FORCEPS, a surgeon's instrument, wherewith dead and corrupt parts are seized, cut, or pulled off, &c. As also foreign bodies extracted out of wounds, &c.

The word literally denotes a pair of tongs.

They are of divers forms; long, crooked, with teeth, with beaks, half-mooned, &c. See *Tub. Surgery*, fig. 14, Tab. III. fig. 31, 34, 43.

Mr. Monro describes and gives a figure of a *forceps*, the mouths of which has on each side two small sharp teeth, which apply close to one another when it is shut. This *forceps*, when shut, may be safely introduced into a gunshot wound, and the blades being immediately opened behind the bullet, the teeth will pierce into the lead, and hold it fast enough to bring it out, though they are not advanced so far as the largest part of it. Med. Edinb. vol. v. art. 41.

Dr. Le Cat has contrived a new *forceps* for the extirpation of tumours, the extraction of stones, &c. for an account of which, see *Phil. Trans.* N° 491. or vol. xlv. p. 60, &c.

The *forceps* is also used for extracting the *fœtus* in cases of pretermatural delivery. The instrument used for this purpose is either straight or curved. The straight *forceps* is used for bringing the head of the child forward, when

on account of its size, or the want of pain, it cannot otherwise be protruded; but the use of them requires great care: and it is observed, that instruments of this kind are never necessary, whilst the head is above the brim of the pelvis, and safely when it hath descended lower. Dr. Hunter absolutely forbids the use of them, if they can possibly be avoided. Those improved by Smellie are the best, who has reduced their length, in order to prevent their being used before the head is low enough. The long curved *forceps* was invented by Smellie, with a view to saving the life of the child, when the body being delivered, the head could not be brought away in the usual manner. These are longer than the first ones, because they are applied, when the head of the child is above the brim of the pelvis. The straight and curved *forceps*, as well as the blunt hook, are used in expedite and facilitate delivery; whereas the cruetcher, which has a hook at its point that is fixed into the part to which it is applied, wounds, and generally kills the child.

FORCE-ELL, in *Mechanics*, is properly a piston, without a valve.

There are several ways of making *forceps*: the most common of all consists of a brass cylinder, a very little less in diameter, at its bottom and top, than the bore of the barrel of the pump, and turned still less at the middle, in order to let in a leather ring or collar (made of a thick leather put round the brass cylinder), which makes it just equal to the bore of the barrel, so as to fit it quite when it is put into it.

The second sort of *forceps* consists of three brass cylinders, which can be screwed together. The middle one ought to be almost equal in diameter to the bore of the pipe, so as to slide in it without any friction. The upper cylinder and the lower must be a little less, and equal to one another. There are two leathers which must be put between them when they are unwound: then it is evident, that if the cylinders be screwed together, and the leathers, which ought to be a little bigger than the brass cylinders, apply themselves folding upwards round the upper cylinder, and downwards round the lower, they will become just equal to the bore of the barrel, and consequently they will hinder any air from getting through the sides of the *forceps*, when it moves up and down in the barrel. The use of the middle brass cylinder is to hinder the leathers from turning themselves back by the motion.

This kind of *forceps* has, above the other, the advantage of having a great deal less friction; and besides, as the leathers, which are applied to it, may be thin ones, they are much smoother than thick ones, which are used in the other.

But the best way of making *forceps*, is to have a plunger, or solid brass cylinder, equal in length to the bore of the pump, and a little less in the diameter than the bore, so that it may move freely in it without any friction. There must be two hollow, short, brass cylinders, or rather rings, at the top of the barrel, which can be screwed together; the upper one must be equal in bore to the barrel, and the lower a little less: there are two leathers, both having in the middle a less hole than in the bore of the pipe; the one must be applied between the barrel and the lower ring, and the other between the same ring and the upper one; and the whole must be screwed together. Then if the solid cylinder or *forceps* be put into it, and moved up and down, it is evident that the two before mentioned leathers, which are applied the one to the barrel and the other to the inside of the hollow cylinder, will hinder any air from getting between them and the solid cylinder.

The advantage of this kind of *forceps* is, that it has no other friction but at the top of the barrel, and that the inside of the barrel need not be smooth, as in other kinds of pumps; but only the outside of the *forceps* must be turned true and polished, which can be done with much more ease, and the lower part must be turned a little round, so that it may be brought into the barrel, without any resistance of the upper leather of the collar or pack-head. See Desaguliers, *Course of Experim. Phil.* vol. ii. p. 161, 162.

FORCEBLE Entry, a violent, actual entry into houses, or lands, &c. with menaces or weapons, whether violent or hurt be offered to any person therein, or not.

FORCEBLE taking, or *detaining*, a with-holding by violence, and with a strong hand, of the possession of land, &c. whereto he who has a lawful right of entry is barred or hindered. See *ENTRY*.

This was formerly allowable to every person distressed, or turned out of possession, unless his entry was taken away or barred by his own neglect, or other circumstance. But this being found very prejudicial to the public peace, it was thought necessary, by several statutes, to restrain

all persons from the use of such violent methods even of doing themselves justice: so that the entry now allowed by law is a peaceable one. By the several Statutes of 15 Ric. II. cap. 2. 8 Hen. VI. cap. 9. 31 Eliz. cap. 11. and 21 Jac. I. cap. 15. upon any forcible entry, or forcible detainer after peaceable entry into any lands or benefices of the church, one or more justices of the peace, taking sufficient power of the county, may go to the place, and there record the force upon his own view, as in case of riots; and upon such conviction, may commit the offender to gaol, till he makes fine and ransom to the king. And the justice or justices have power to summon a jury, to try the forcible entry or detainer complained of; and if the same be found by that jury, then, besides the fine on the offender, the justices shall make restitution by the third of the possession, without inquiring into the merits of the title; for the force is the only thing to be tried, punished, and remedied by them; and the same may be done by indictment at the general sessions. But this provision does not extend to such a endeavour to maintain possession by force, where they or their ancestors have been in the peaceable enjoyment of the lands and tenements for three years immediately preceding.

FORCIBLE abduction and marriage, vulgarly called *kidnaping* an heiress. By stat. 3 Hen. VII. cap. 2. it is enacted, that if any person shall, for lucre, take any woman, maid, widow, or wife, having violence either in goods or lands, or bring her against her will, or her ancestors, contrary to her will, and afterwards she be married to such murderer, or by his consent to others, or defiled; such person, and all his accessories, shall be deemed principal felons; and by stat. 19 Eliz. cap. 9. the benefit of clergy is taken away from all such felons, except accessories after the offence. See *MARRIAGE*.

FORCING, in the *Wine-trade*, a term used by the wine-cooper for the *fining* down wines, and rendering them fit for immediate draught.

The principal inconvenience of the common way of *fining* down the wines-wines by singlings, and the use by which of eggs, is the slowness in the operation; these ingredients not performing their office in less than a week, or sometimes a fortnight, according to the weather proves favourable, cloudy or clear, windy or calm: this appears to be matter of constant observation. But the wine-merchant frequently requires a method that shall, with certainty, make the wines fit for falling in a few hours. A method of this kind there is, but it is kept in a few hands a valuable secret. Perhaps it depends upon a prudent use of a tartarized spirit of wine, and the common *finings*, as occasion is, along with gypsum, as the principal; all which are to be well stirred about in wine, for half an hour before it is tastered to rest. Shaw's Lectures, p. 208.

FORCING, among *Gardeners*, is used for producing ripe fruits from trees before their natural season. The method of doing it is this: a wall should be erected ten feet high; a border must be marked out on the fourth side of it, of about four feet wide, and some stakes must be fastened into the ground all along the edge of the border, these should be four inches thick. They are intended to rest the glass-lights upon, which are to slope backwards to the wall, to shelter the fruit as there shall be occasion; and there must be at each end a door to open either way, according as the wind blows. The frame should be made moveable along the wall, that when a tree has been forced one year, the frame may be removed to another, and so on, that the trees may be each of them forced only once in three years, at which rate they will last a long time. They must be always well-grown trees that are chosen for forcing, for young ones are soon destroyed, and the fruit that is produced from them is never so well tasted. The frame most proper for this management are the azar, or small white nunges, the Alburns, the early Newington, and the brown nunges peaches; Mr. Fairchild's curran, and the elugo and Newington nektars; the masculine apricot, and the May duke and May-cherry. For grapes, the white and black sweet-water are the properest; and of gooseberries, the Dutch white, the Dutch early green, and the walnut gooseberry; and the large Dutch white, and large Dutch red currants.

The dung, before it is put to the wall, should be laid together on a heap for five or six days, that it may heat uniformly through; and when thus prepared, it must be laid four feet thick at the base of the wall, and go sloping up, till it is two feet thick at the top. It must be laid at least within three or four inches of the top of the wall, and when it sinks, as it will sink two or three feet, fresh dung must be laid; for the first heat will do little more than just swell the blossom-buds. The covering of the trees with glasses is of great service, but they should be taken off to admit the benefit of gentle showers to the trees,

and the doors at the ends should be either left entirely open, or one or both of them opened, and a mat hung before them, at once to let the air circulate and to keep out the frosts.

The dung is never to be applied till toward the end of November, and three changes of it will be sufficient to ripen the cherries, which will be very fine in February. As to the apricots, grapes, nektars, peaches, and plums, if the weather be mild, the glasses are to be opened to let in sunshine or gentle showers.

If a row or two of earlet Strawberries be planted at the back of the frame, they will ripen in February, or the beginning of March; the vines will blossom in April, and the grapes will be ripe in June.

It should be carefully observed not to place early and late ripening fruits together, because the heat necessary to force the late ones will be of great injury to the early ones, after they have fruited.

The mainline apricot will be ripe in the beginning of April, the early nektars will be ripe about the same time, and the forward sort of plums by the latter end of that month. Gooseberries will bear fruit fit for sale in January or February, and will ripen in March, and currants will bear ripe fruit in April.

The treaciness must be planted so distant at their walls as at others, for they do not shoot so freely as in the open air; if they are more free alunder it is sufficient. They should be pruned about three weeks before the heat is applied. See *MORT-BUD*.

FORCING POWER. See *POWER*.

FORCICIDIA, in *Antiquity*, a religious feast among the Romans, held on the fifteenth of April: thus called from the Latin *foris*, a cow by itself, and *cida*, a slaughter, or *foris*, because such cows were herein sacrificed to the goddess Tellus, or the earth.

Foris, a cow and calf, is formed, according to Ovid, from *foris*, I bear; or rather, as Scaliger and Salmastius imagine, from the Greek *foros*, *foros*, the same.

Varro writes, that there were several of these cows sacrificed in the Curia. And Livy and Hælianus relate that there was one in each Curia; so that there were thirty in all; which is confirmed by Ovid, *Fæstorum lib. ii. v. 631*.

The *foricidia* were first instituted by Numa, on occasion of a general barrenness among the cattle. Ovid gives a particular description of the ceremony. In the passage above quoted: he adds, that part of these cows were sacrificed in the temple of Jupiter; that is, in the Capitol.

FORE, applied to a ship, denotes all that part of a ship's frame and machinery which lies near the stem.

FORE and aft is used for the whole ship's length, or front and to end.

FORE-BULWARK is the *BOWLING* of the fore-sail.

FORE-CLEET of a ship, is a short deck placed in the fore part of the ship, above the upper deck. See *Tab. Ships*, fig. 2, *let. B. C.*, No. 23.

It is usually terminated, both before and behind, by a breast-work in vessels of war, the foremast end forming the top of the *main-deck*, and the hind-part reaching to the after-part of the fore-chain.

FORE-CASTLE is the fore-part of the ship.

FORE-CLOSED, in our ancient *Latin*, signifies barred, shut out, or excluded for ever; as, when the equity of redemption on *MORTGAGES* is barred.

FOREFANG, or **FORETEND**, in our old Writers, is the taking of provision from any one's lands or markets, before the king's purveyors are served with necessities for him. The word is Saxon, compounded of *fore*, ante, and *fangen*, *prendre*.

FORE-FINE of a ship, is a piece of timber that terminates the keel at the fore end. It is connected by a scarf to the extremity of the keel, of which it makes a part; and the other end of it, which is bent upwards into a kind of knee or crook, is fastened to the lower end of the stem, of which it makes a part, being also called the *stern*.

FORE-FOOT, in the *Sea-Language*, is when one vessel falls or lies across another's way.

As if two ships being under sail, and in ken of one another, one of them lies in a course, with her stern to much weather of the other, that if both hold on, the windward ship will run ahead of the other; such ship is said to lie with the other's fore-foot.

Though, as soon as the has passed, they say, she is gone out ahead.

FOREGAVEL, *forghabum*, in our old Writers, is used for a small referred rent in money, or quit-rent.

FOREGOERS, in our old Writers. The king's purveyors were thus called from their going before the king to his household. 26 Edw. III. 5.

FOREHEAD. *Wounds of the FOREHEAD.* After a wound in this part is cleansed from grumous blood and extraneous bodies, if any were left there, it should be dressed with balsam of Peru, or some other vulnerary balsam; the lips of the wound are then to be kept together by long slips of sticking plaster, and over this a vulnerary plaster is to be laid. Where the wound is large, these plasters will not be sufficient to bring on an even cicatrix; therefore, to forward this end, the wound should be sprinkled with a compound powder of camfrey-root and gum tragacanth and aloe, and with gum sarcocolla in powder; and then the plasters, compresses, and proper bandages, are to be applied. The bloody future is never to be used in any wound of the face it can be avoided, because the stitches increase the number of the scars. If a wound of the forehead is made in a straight line, the uniting bandage will be of great service in forming a fine cicatrix: but if the forehead is wounded transversely, and the fibres of the frontal muscle are divided, it occasions a great deformity; for the power of lifting up the eye-brows, and of contracting the skin of the forehead ceases. In this case, after cleaning the wound, it is best to unite it with a stitch or two, dressing it with a vulnerary balsam, and laying on sticking plasters, securing all with a proper bandage, and continuing the patient to keep himself still. In young and healthy persons, the fibres of the muscles join and unite when this method is used, without coming to a suppuration. Heister's Surg. p. 78.

FOREHEADS of a ship. See BREAST-BUITS.

FOREHEADS. See JEEBS.

FOREHEADS, in a ship. See BITE.

FOREIGN, something extraneous, or that comes from abroad.

The word is formed from the Latin *foris*, *divers*, or *foris*, out of doors, or from *foris*, *foris*.

Foreign minister, *foreign* prince, *foreign* goods, &c. are those belonging to other nations. See MINISTER, &c. *Foreign* to the purpose, signifies a thing remote or impertinent.

Matter is *foreign* to the idea of space, i. e. it is not inherent therein, but adventitious thereto.

Foreign plants are particularly called *exotica*. *Foreign* fossils, see FOSSIL. *Foreign* nation, see NATION. *Foreign* cause, see CAUSE.

In some universities they give the appellation *foreign doctor*, *doctores foris*, to such as do not reside in the place, or the university; but take degrees to go and live elsewhere, and in other countries.

In the life of St. Paul, bishop of Verdun, written by an anonymous author, and published from a MS. about four hundred years old, by Dandanus, we meet with *foris* *propheta*, for a prophet who lives in another part. The same Dandanus notes, that St. Ambrose used the word *foris* for exterior.

FOREIGN, or *FOREIGN* *Traitte*, is a duty belonging to the king of France, of one-twentieth of the value of all goods imported, or exported out of the kingdom.

FOREIGN, is used in Law, in several senses, and joined with divers substantives. Thus,

FOREIGN answer, is such an answer as is not triable in the country where it is made.

FOREIGN attachment. See ATTACHMENT.

FOREIGN bill of exchange. See BILL.

FOREIGN matter, in Law, is matter triable in another country, or matter done in another country.

FOREIGN assessor, or *assessor*, is an officer in the exchequer, to whom all sheriffs or bailiffs do repair to be appoyed by him of their given wax, after they are appoyed of their fums out of the pipe office; and who from thence draws down a charge upon one of them to the clerk of the pipe.

His business is to examine the sheriff's excheats with the record, to ask the sheriff what he says to every particular fur therein.

FOREIGN plea, is a refusal of the judge as incompetent, because the matter in hand was not within his precinct.

FOREIGN persons, serving two years on board British ships, whether of war, trade, or privateers, during the time of war, shall be deemed natural born subjects. But the persons so naturalized are not capable of being of the privy council, or members of parliament, or of taking any place of trust, civil or military, or to have any grant from the crown of lands. Stat. 13 Geo. II. cap. 3. sect. 2.

FOREIGN service, is such service whereby a mean lord holdeth of another, without the compass of his own fee; or that which a tenant performeth, either to his own lord, or to the lord paramount, out of his own fee.

FOREIGN service is also used to denote military service performed to foreign states. The Stat. 3 Jac. I. cap. 4. makes it felony for any person to go out of the realm to serve any foreign prince, without having first taken the oath of allegiance before his departure; and it is also felony for

any gentleman, or person of higher degree, who hath borne any office in the army, to go out of the realm to serve such foreign prince or state, without previously entering into a bond with two foremen not to be reconciled to the foe of Rome, or enter into any conspiracy against his natural sovereign. And by Stat. 9 Geo. II. cap. 30. enforced by 29 Geo. II. cap. 17. if any subject of Great Britain shall enlist himself, or any person shall procure him to be enlisted, in any foreign service, or detain or embark him for that purpose, without licence under the king's manual, he shall be guilty of felony without benefit of clergy; but if the person so enlisted or enticed, discover his seducer within fifteen days, so that he may be apprehended and convicted of the same, he shall be indemnified. By Stat. 29 Geo. II. cap. 17. to serve under the French king, as a military officer, is felony without benefit of clergy; and to enter into the Scotch brigade, in the Dutch service, without taking the oaths of allegiance and abjuration, incurs a forfeiture of five hundred pounds.

FOREIGNERS are the natural born subjects of some foreign prince. *Foreigners* residing seven years in the British plantations without any longer absence than two months at one time, and taking the oaths, are to be deemed natural born subjects. But, excepting Quakers and Jews, all other persons must receive the sacrament in some protestant or reformed congregation in Great Britain, or the colonies; a certificate whereof must be produced at the time of taking the oaths. 13 Geo. II. cap. 7. sect. 2. See NATURALIZATION.

FOREJUDGED the court, is when an officer of any court is banished, or expelled the same, for some offence; or for not appearing to an action by bill filed against him: in which latter case, he is not to be admitted to officiate, till he appear to the bill. Anno 2 Hen. IV. cap. 8. He shall lose his office, and be forejudged the court, &c. *Forejudicium interdictum of main judicium* Spel.

FOREJUDGER, in Law, signifies a judgment, whereby a man is deprived, or put by a thing in question.

FORELLA, in Ichthyology, a name given by Vigulus and others to the trout.

FORE-LOUGH, in the Sea-language, a piece of wood, carved in figure of a man's head, and fast belted to the beams upon the second deck.

FORELAND, or *FOREMANT*, in Navigation, a point of land jutting out into the sea.

FORELAND, in Fortification, is a small space of ground between the wall of a place, and the moat, called also *BERMET*, and *liniera*.

FORELOCKS, in a Ship, are little flat wedges, like pieces of iron, used at the ends of bolts, to keep them from flying out of the holes.

FORELOIN, among Hunters, is when a hound goes before the rest of the covey, meets chase, and goes away with it.

FORELORN hope, in an Army, an almost obsolete expression. See *EVANS* *perdu*.

FORE-mast of a ship, is a round large piece of timber, seated in her fore-part, on which is born the fore-mast, and fore-top-mast-yard. See *Tub. Ship* fig. 1. N^o 81. See MAST.

FORE-mast-men, in a Man of War, those on board that take in the top-sails, sling the yards, furl the sails, browse, trice, and take their turn at the helm, &c.

FORENSIC service. See SERVICE and FOREIGN.

FORENSIS sign. See TOCS.

FORE-rate, in Sea-language. See RATE.

FORE-reach, in Sea-language. The seamen lay one ship *fore-reach* upon another, when both sailing together, the falls better, or outgates the other.

FORE-sail, the sail of the fore-mast. See SAIL.

FORESHOCKE, *divulsi*, anciently signified as much as *forshaken* in modern language.

It is especially used in one of our statutes, for land or tenements granted by the lord, for want of services due from the tenant; and is quietly held and possessed beyond the year and day.

As if we should say, that the tenant, who seeing his lands or tenements taken into the lord's hand, and possessed so long, takes not the course appointed by law to recover them, does, in due presumption of law, disavow or forsake all the right he has to them. In which case, such lands shall be called *forshokete*, says the Stat. 10 Ed. II. cap. 1.

FORE-shrouds. See SHROUDS.

FORESKIN. See PREPUCE.

FORE-slay. See SLAY.

FOREST, filus, in Geography, a great wood; or a large extent of ground covered with trees.

The word is formed of the Latin *foris*, which first occurs in the Capitulars of Charlemagne, and which itself is derived from the German *forst*, signifying the same

thing. Spelman derives it from the Latin *foris* *reflat*, by reason *foris* are out of towns. Others derive *foris* from *foris*, *q. d. foris*, *quod sit tuta statim foris*, as being a safe station, or abode, for wild beasts.

The Caledonian and Hercynian *foris* are famous in history. The first was a celebrated retreat of the ancient Picts and Scots; the latter anciently possessed the greatest part of Europe; particularly Germany, Poland, Hungary, &c. In Caesar's time it extended from the borders of Asia and Switzerland to Transylvania, and was computed sixty days journey long, and nine broad: some parts or cantons thereof are still remaining. The *foris* of Dean in Gloucestershire, is famous for the iron works therein.

The ancients adored *foris*, and imagined a great part of their gods to reside therein: temples were frequently built in the thickest *foris*, the gloom and silence whereof naturally inspired sentiments of devotion, and turned men's thoughts within themselves.

For the like reason, the ancient Druids made *foris* the place of their residence, and performed their sacrifices, instructed their youth, and gave laws therein. See DRUIDS.

FOREST, in a Law-sense, is defined a certain territory of woody grounds and fruitful pastures, privileged for wild beasts and fowls of *foris*, chase, and warren, to rest and abide in, under the protection of the king, for his recreation and delight; bounded with unremovable marks and mares, either known by matter of record or prescription; replenished with wild beasts of venery, or chase, and with great covert of vert for succour of the said beasts: for preservation and continuance whereof, with the vert and venison, there are certain peculiar laws, privileges, and officers.

The properties and characters of a *foris* are, first, that it cannot be in the hands of any but the king; because none else had power to constitute such commissions as are necessary to the being of a *foris*, beside the king; as, particularly, that of justice in eyre of the *foris*. And yet the abbot of Whithy had a *foris* by grant of king Henry II. and king John, with all officers incident thereto.

The second character is the courts belonging thereto, which are, the *justices*, and the *ward*, held every third year; the *foreman*, held twice every year; and the *attainder*, once every forty days.

The third characteristic is the officers belonging thereto, for preservation of the vert and venison; as, the justices of the *foris*, the warden or keeper, ranger, verderer, foresters, agisters, regarders, bailiffs, beades, &c. See each under its proper article, JUSTICE of the *foris* KEEPER, &c.

But the most essential mark of a *foris* is the swanmote, which is no less incident thereto than the court of *pye*-powder to a fair. If that fail, it ceases to be a *foris*, and commences a chase. See SWANMOTE.

The way of making a *foris* is thus: certain commissioners appointed under the great seal, view the ground intended, and fence it round; this being reported in chancery, the king causes it to be proclaimed throughout the county where the land lies, that it is a *foris*, and is thenceforth to be governed by the laws of the *foris*; and prohibits all persons from hunting therein, without his leave.

New *foris* in Hampshire, history tells us, was made by the destruction of twenty-two parish-churches, and all the villages, manors, chapels, &c. for the space of thirty miles together. Beside New *foris*, there are now subsisting sixty-eight *foris* in England, thirteen chases, and eight hundred parks.

Our ancient Norman kings were the first who inclosed *foris*, and settled the jurisdiction thereof. In the course of a few reigns from the Conquest, no less than sixty-eight *foris* were inclosed; the strictest laws were made to secure them, and the severest penalties inflicted on all trespassers thereon.

William the Conqueror decreed the eyes of any person to be pulled out, who took either a buck or hart. William Rufus made the stealing of a doe a hanging matter; the taking of a hare was fined at 20s. and a coney at 10s. Eadmer adds, that fifty persons of fortune, being apprehended by that last prince for killing his bucks, were forced to purge themselves by the fire of ordeal, &c.

Henry I. made no distinction between him who killed a man and him who killed a buck; and punished those who destroyed the game, though not in the *foris*, either by forfeiture of their goods, or loss of limbs; though Henry II. remitted it for a temporary imprisonment.

Richard I. revived the old discipline of gelding and pulling out the eyes of those convicted of hunting in the *foris*; but he afterwards relaxed a little, and was contented to make such convicted signify the realm, or be committed, or pay a fine.

FOREST, *affine* of the. See ASSIZE.

FOREST, *charter* of the. See CHARTER of the *foris*.

FOREST, *drift* of the. See DRIFT.

FOREST, *foot* of the. See FOOT.

FOREST, *keeper* of the. See KEEPER.

FOREST, *perambulation* of the. See PERAMBULATION.

FOREST, *repetition* of the. See REPETITION.

FOREST, *waste* of the. See WASTE.

FOREST is also used adjectively. The *foris* cities of the empire are four cities situate in the ancient Black *foris*, or Silva Nigra, a part of the ancient Hercynian *foris*, viz. Rhinfield, Waldsilt, Seckingen, and Lauffembourg. But now, since the bounds of the Black *foris* are contracted, these cities are out of the limits thereof.

FOREST-LAW. The *foris* laws are peculiar laws, different from the common law of England.

Before the making of Charta de *foris*, in the time of king John and his son Henry III. confirmed in parliament by a Henry III. offences committed therein were punished at the pleasure of the king, in the severest manner. By this charter, many *foris* were disafforested and stripped of their oppressive privileges, and regulations were made for the government of those that remained; particularly, killing the king's deer was made no longer a capital offence, but only punished by fine, imprisonment, or abjuration of the realm; yet even in the charter there were some grievous articles, which the clemency of later princes have since by statute thought fit to alter *per officia* foreste.

And to this day, in trespasses relating to the *foris*, *voluntas reputabitur pro facto*; so that if a man be taken hunting a deer, he may be arrested as if he had taken a deer. The forester may take and arrest a man, if he be taken either at dog-draw, stable-hand, back-bear, or bloody-han; notwithstanding that three of these be only presumptions. See DOG-DRAW, STABLE-HAND, &c. See also BLACK *ad*.

FOREST-TREES. Many are wholly averse to pruning *foris*-trees; but though it is to be done with care, and under proper regulations (see LOPPING), yet it is by no means to be wholly omitted. It may be observed in *foris* and large woods, that for one tree which thrives well, there are twenty that grow faulty, and all this is owing to the want of pruning or lopping in a proper manner; for this, when wisely executed, is a renewal of their age, and of their growth too; the want of it being what occasions trees to run out into suckers, and to load themselves with useless boughs, which draw away the sap from the upper part, and make it grow knotty and distempered, and usually covered with moss.

If a tree grow crooked, the business of the owner is to cut it off sloping at the crooked place, and nurse up some young bough that grows upright from that part, and it will make it a straight body. This is not to be done when trees are very large, but the careful owner will not suffer them to grow very large without doing it. Mortimer's Husbandry, vol. II. p. 84.

There is also another caution, which is, that soft woods do not bear this heading so well as the harder, and the beech in particular is less able to bear it than any other. If young trees grow but a little crooked, they may be cured by only thinning up the branches while young, all the way up the body till past the crooked part. When cattle have cropped any of the shoots of young trees, they should be cut off close to the body, for they not only never grow well after it, but the cattle usually leave a drivel where they have bitten, which sometimes occasions a rot of the branch, and endangers the whole tree. The best time for pruning young *foris*-trees is in February; and it should be done where there is occasion every year, or at the utmost every second year, so that the tree may be able to overgrow the knot, and the place not liable to put out suckers, because the sap had had no great resource to it. When it is necessary to cut off a bough of any bigness, there must always be given a chop or two underneath, opposite to the part where it is cut above, otherwise the weight of the bough, in its fall, is apt to strip off the bark from the remaining stump, to the great detriment of the tree. When trees are kept for pollards, they must be regularly lopped every two years; for if the branches are suffered to grow longer than that, they are apt to be faulty at the wound when cut off, and to let in water, the consequence of which will be the decay of the tree, and it can no more bear any great quantity of branches at top.

The general growth of trees in thickness of the body, is from one inch to two inches in a year. The large and small increase much in the same proportion in this respect, if they are in a like thriving condition. The goodness of soil will make a great difference in this growth, as has been experienced by Mortimer, who observed, that the common increase of the oak is about an inch and a quarter in thickness in the body in a year; but a large

was that grew in one of his own ploughed fields, where the earth was silted and manured every year, and that often had cattle lying under it, and dunged about its roots, grew annually no less than four inches in thickness. This shews the great advantage of digging about the roots of trees, and dunging them, and may serve as a hint for a very practicable method of increasing the growth of trees on occasion. The killing of weeds that grow about the roots of trees, is one great method of increasing the growth; but there is an error which I have here run into on this principle, that is to be carefully avoided. These people observing the great damage that weeds do to the trees, have supposed that shrubs and underwood in hedges and coppices do the same; but this is a mistake. Experience shews, that *weeds* thrive better and grow faster in coppices than when they stand single; and it is certain that, next to digging and dunging about the roots, the growth of underwood about the tree is the best method of promoting its increase. These shrubs keeping the earth moist about the roots of the tree, and covering all the earth about with their falling leaves and rotten branches, which break off at times, and which are the richest of all manure: a little rotten wood blended among even a bad soil, converting it into the nature of garden-mould. Morimer's Husbandry, vol. ii. p. 86. See TREES and TIMBER.

FORESTIER, *transplanter* of trees. See TRANSPLANTING.

FORE-SHAFT, an instrument used at sea, for taking the altitudes of heavenly bodies.

The *fore-shaft*, called also *cross-shaft*, takes its denomination hence, that the observer, using it, turns his back towards the object, in contradistinction to the back-shaft, where he turns his back to the object. The *fore*, or cross shaft, represented in Tab. Navigat. fig. 11. consists of a brass square shaft, AB, graduated like a line of tangents, and four crosses, or vaneas FF, EE, DD, CC, which slide thereon. The first and shortest of these vaneas, FF, is called the *ten cross*, or *vane*, and belongs to that side of the instrument, whereon the divisions begin at three degrees, and end at ten. The next longer vane, EE, is called the *thirty cross*, belonging to that side of the shaft, wherein the divisions begin at ten degrees, and end at thirty; called the *thirty shaft*. The next vane, DD, is called the *sixty cross*, and belongs to the side where the divisions begin at twenty degrees, and end at sixty. The last, and longest, CC, called the *ninety cross*, belongs to the side whereon the divisions begin at thirty degrees, and end at ninety.

Fore-shaft, *use of the*. The great use of this instrument is to take the height of the sun, and stars, or the distance of two stars; and the ten, thirty, sixty, or ninety crosses, are to be used according as the altitude is greater, or lesser; that is, if the altitude be less than ten degrees the ten cross is to be used; if above ten, but less than thirty, the thirty cross is to be used, &c.

Note, for altitudes greater than thirty degrees, this instrument is not so convenient as a quadrant, or semicircle.

Fore-shaft, *to observe an altitude by the*. Apply the flat end of the shaft to your eye, and look at the upper-end of the cross for the centre of the sun, or star, and at the lower end for the horizon. If you see the sky, instead of the horizon, slide the cross a little nearer the eye; and if you see the sea, instead of the horizon, slide the cross farther from the eye: and thus continue moving, till you see exactly the sun or star's centre by the top of the cross, and the horizon by the bottom thereof.

Then the degrees and minutes, cut by the inner edge of the cross, upon the side of the shaft, peculiar to the cross you use, give the altitude of the sun or star.

If it be the meridian altitude you want, continue your observation as long as you find the altitude increase, still moving the cross nearer to the eye.

By following the meridian altitude thus found, from ninety degrees, you will have the zenith distance.

To mark accurately, an allowance must be made for the height of the eye above the surface of the sea, viz. for one English foot, 1 minute; for five feet, 21; for ten feet, 31; for twenty feet, 51 for forty feet, 7, &c.

These minutes subtracted from the altitude observed, and added to the zenith distance observed, give the true altitude, and zenith distance.

Fore-shaft, *to observe the distance of two stars, or the moon's distance from a star, by the Fore-shaft*. Apply the instrument to the eye, and looking to both ends of the cross, move it nearer, or farther from the eye, till you see the two stars; the one on the one end, and the other on the other end of the cross: then the degrees and minutes cut by the cross on the side proper to the vane in use, give the stars distance.

FORESTAGE, **FORESTAGION**, in our Ancient Customs, an obnoxious duty, or service, paid by the forester to the king. In Britany, Lobineau observes, the office of foresters

was held by gentlemen of the first rank, who for their *forestage* were obliged to furnish the lord, when he kept open house, with cups and spoons.

FORESTAGE also seems to have been used for a duty payable to the king's foresters. *Et sui quatuor de tholaco, & pagano, &c. de forestage*, &c. Chart. Edw. I.

It may likewise be taken for a right to use the forest, or a making of reasonable inclosures.

FORESTALL, or **FORESTALL**, in Domesday were **FORESTALL**, an intercepting in the highway; or stopping, or even including a passage therethrough.

The word is formed of the Saxon *forst*, *forest*, and *stall*, *stallan*. In the laws of Henry I. the first use of the word is thus explained: *forestell est, si quis in transverso intercal, vel in viam expellat, ut quilibet iusticiarius sciat*.

FORESTALLER, a person who *forestalls* the market, or buys up goods upon the road.

FORESTALLING, the buying or bargaining for corn, cattle, or other merchandise, by the way, before it reaches the market, or fair, to be sold; or by the way, as it comes beyond the seas, or otherwise, toward any city, port, haven, or creek, of this realm, with design to take advantage thereof, and sell it again at a more advantageous and dear rate.

Fiets says, it signifies *obstructionem viæ, vel impedimentum viamque & viam contrariam*.

By the sixth and sixth *statute*, cap. 12. any buying or contracting for merchandise, victuals, or other thin, whatsoever, in the way, coming by land or water to any fair or market, or to any port, &c. or be sold, or carrying the same to be bought, or disposing thereof by word, letter, or otherwise, or otherwise, from bringing such things to market, or purchasing them to enhance the price, after they are brought thither: is *forestalling*; and the party guilty of any offence of *forestalling*, &c. upon conviction at the quarter sessions by two witnesses, on bill, information, presentation, &c. shall, for the first offence, lose the goods he bought, or the value of them, and suffer two months imprisonment; for the second offence, he shall forfeit double the value, and be imprisoned six months; and for the third offence, he shall lose all his goods, be put upon the pillory, and be imprisoned at the king's pleasure.

FORESTALLING is particularly, used in Chompton, for stopping a deer broken out of the forest, and preventing its returning home again; or, a lying between him and the forest in the way he is to return.

FORESTER, a sworn officer of the forest, appointed by the king's letters patent to watch the forest, and watch the vert and venison; as also to attach and prevent all trespasses against both, within his bailiwick or walk, at the forest-court, to be punished according to their offences.

Though the letters patent of a *forester* be originally only granted *quoad hunc locum se possit*; yet they are granted to some and their heirs, who are hereby called *foresters in fee*.

Sir William Temple relates, that the Franks having subdued all Gaul, their princes reduced the forests into a kind of government, and gave the quality of *forester*, with part of the province, to the bravest of their captains.

This quality of lord-forester held till the time of Charles-magne, or, according to others, of Charles the Bold, in whose time Flanders being erected into a county, the title of *forester* was changed into that of count.

FORESTED are, in *diving*, are got out of earth and dirt that has been washed, and ore taken out of it before.

FORE-UP of a ship. See TOW.

FORE-UP-MOST is half the length of the fore-mast (see TOW-SHIP, fig. 1. II. 102.) and the fore-top-gallant-mast half the length of the fore-mast. See TOW-MAST and MAST.

FORE-UPPER, Striking out the *fore-upper* is a metaphor.

See FORE-UPPER.

FOREUTURE originally signifies a transgression or offence against some penal law.

The word is formed of the late Latin *forisfuture*, whence *forisfuture*, and *forisfuture*, and the French *forisfuture*. *Forisfuture* comes of *forisfuture*, which, according to Isidore, signifies *is future*, or *future*, *future*, *future*, *future*, and which is not improperly derived of *foris*, out, and *future*, to do, &c. an action out of itself, or contrary to the rules.

But with us, it is now more frequently used for the effect of such transgression, or the losing some right, privilege, estate, honour, office, or estate, in consequence thereof, than for the transgression itself, as *forisfuture of estate*, *forisfuture of goods*, &c. A fee becomes vacant by the *forisfuture* or rebellion of the vassal.

Goods *forisfuture*, and goods confiscated, differs: these which have a known owner, who has committed some offence, whereby he loses his goods, are said to be *forisfuture*; those which an offender disavows, as not his own, and which are not claimed by any other, are said to be confiscated.

confiscated, stat. 25 Edw. III. Add, that *forfeiture*, or *forfeit*, is more general; and confiscation more particular, being principally used for such as *forfeit* only to the king's exchequer.

FORFEITURE, *full, plena forisfactura*, called also *plena vita*, is a *forfeiture* of life and members, and all else that a man has.

This obtains in criminal cases, as where a person is attainted of treason, felony, &c. There is also a *forfeiture* of lands, &c. in civil cases. There are various degrees and various means, whereby lands, tenements, and hereditaments, may be *forfeited*. 1. By crimes and misdemeanors; of this, the principal offences that induce a *forfeiture* of lands and tenements to the crown, are treason, felony, misprision of treason, perjury; drawing a weapon on a judge, or striking any one in the presence of the king's principal courts of justice, and popish recusancy, or non-observance of certain laws enacted in restraint of papists. 2. By *attestations*, contrary to law, which may be in mortmain to an alien, on account of his incapacity to hold the lands so alienated; and by particular tenancy, when the alienations are greater than the law enables them to make, and disvest the remainder or reversion; in which case they become *forfeitures* to him whose right is hereby injured: there is also an alienation by disclaimer. 3. By non-performance of conditions, annexed to estates, either express or legally implied. 6. By *waiver*. 7. By breach of *corporate* customs. 8. By *bankruptcy*. Goods and chattels, likewise, are totally *forfeited* by conviction of high treason, or misprision of treason; of petit treason; of felony in general, and particularly of felony *de se*, and of man-slaughter, may, even by conviction of excusable homicide; by outlawry for treason or felony; by conviction of petit larceny; by flight in treason or felony, even though the party be acquitted of the fact; by standing mute, when arraigned of felony; by pretended prophecies, upon second conviction; by owing by the residing abroad of artificers; and by challenging to fight on account of money won at gaming. This *forfeiture* commences from the time of conviction, and not the time of committing the fact, as in *forfeitures* of real property. However, a fraudulent conveyance of chattels, between the time of committing the fact and conviction of the offender, to defeat the interest of the crown, is made void by statute 13 Eliz. cap. 5. There are also various other *forfeitures* inflicted, by special statutes, for particular crimes and misdemeanors, some of which are made in *se* or offences against the divine law, either natural or revealed; but by far the greatest part are *male prohibita*, or such as derive their guilt merely from their prohibition by the laws of the land; as *the forfeiture* of 400. per month by the stat. 5 Eliz. cap. 4. for exercising trade without having served *fecum*, years apprenticeship to it; and the *forfeiture* of 100. by 9 Ann. cap. 29. for printing an almanack without a stamp. Blackl. Com. vol. i. p. 267, &c. 420, &c. vol. ii. p. 570, &c. 470, &c.

The true reason of any *forfeiture* for crimes, says Judge Blackstone, is this: that all property is derived from society, being one of those civil rights which are conferred upon individuals, in exchange for that degree of natural freedom, which every man must sacrifice when he enters into social communities; if, therefore, a member of any national community violates the fundamental contract of his association, by transgressing the municipal law, he *forfeits* his right to such privileges as he claims by that contract; and the state may very justly reclaim that portion of property, or any part of it, which the laws have before assigned him. Hence, in every offence of an atrocious kind, the laws of England have exacted a total confiscation of the movables or personal estate; and in many cases a perpetual, in others only a temporary, loss of the offender's immovables or landed property; and have vested them both in the king, who is the person supposed to be offended, being the one visible magistrate in whom the majesty of the public resides. Blackl. Com. vol. i. p. 299.

FORFEITURE of marriage, *forisfactura maritagi*, a writ, which formerly lay against him, who, holding by knight's service, and being under age, and unmarried, refused her whom the lord offered him, without his disparagement, and married another.

FORTEX, in *Surgery*, a pair of scissars wherewith things may be cut.

The word is sometimes also used for pincers, nippers, or pliers; and is often confounded with *forcers*. Blanchard and, after him, Quincy, describes a *forfex* as an instrument for drawing teeth.

FORFICULA. See *Ears-wig*.

Vol. II. N° 138.

FORFICULA marina, the *seaw-wig*, a name given by others to an insect frequently found about the sea-shores; and having some sort of external resemblance to the common *ear-wig*. It is of the size of the common *ear-wig*, and is of a mixed colour, of a deep black and a silvery white. The frontiers are somewhat gibbous, the eyes standing close to one another on the summit of the head; the antennae are long and very denser. It has eight pair of legs on the anterior part of the body, and eight pair more at the hinder part, and there are three or four bristles at the tail. It moves about very nimbly, and lives on rocks and among stones.

FORFIELD, in *Mineralogy*, is the farthest place that a man has wrought in his ground; at the end of a mine above ground.

FORGE, properly signifies a fire furnace, wherein smiths, and other artificers, in tinning steel, &c. heat their metals red-hot, in order to temper and render them more malleable and manageable on the anvil, &c.

We say, a *smith's forge*, *blastsmith's forge*, *cutler's forge*, *locksmith's forge*, &c. The *forge* used by the several operators in iron is very simple, we shall instance in that of the blacksmith, to which all the rest are reducible.

The hearth, or fire-place, is a mass of brick, about two feet six inches higher than the back of the *forger's* built-up to the chimney, and is inclosed over the fire-place with a horse, which leads into a chimney, to carry away the smoke. In the back of the *forge*, against the fire-place, is a thick iron plate, with a taper pipe fixed therein, about five inches long, called the *tail*, into which the nose or pipe of the bellows is received: the vit of this plate and towel is, to preserve the pipe of the bellows, and the back of the hearth from being burnt. Right before the back, at about two feet distance, is the trough, filled with water, to wet the coals with, and thereby increase their force, so also to quench the iron in. Behind the back of the *forge* is placed the bellows, one of whose boards is fixed so, that it moves not, either upward or downward; and the other is fixed a rope, chain, or even a rod, which rises perpendicularly, is fixed to a cross piece, called the *razor*, which moving on a kind of fulcrum near the middle, serves as a handle. By drawing down this handle, the moveable board of the bellows rises, and, by a considerable weight at the top of its upper side, it sinks down again, and, by this alternate agitation, performs the necessary motions of a pair of bellows. See *Bellows*.

Basins and copperlinth *forges* differs but little from that already described; only that it is smaller, and that nothing is burnt in it but charcoal, the metals used by these operators not working well with pit-coal.

Forge is also used for a large furnace, wherein iron ore, or even of the mine, is melted down.

But this is not so properly called a *forge* as a furnace. *Forge* is more properly used for another kind of furnace wherein the iron ore, melted down and separated in a former furnace, and there cast into form and pigs, is heated, and fused over again, and beaten downwards with large hammers, and thus rendered more soft, pliable, and fit for use.

Of these *forges* there are two kinds, which the iron successfully passes through, before it comes to the smith. The first is called the *finery*, where the pigs are worked into gross iron, and prepared for the second, which is called the *chafery*, where it is farther wrought into bars fit for use.

FORGE-mill. See *MILL*.

FORGE, travelling, in the *Train of Artillery*, is a kind of portable smith's shop, by means of which any necessary work may be performed on a march, as well as in camp. This kind of *forge* has been formerly fixed in a carriage with two wheels, and wooden supporters, to prop the *forge* when used; but they are now commonly made with four wheels, so that they stand more firmly, and are more easily removed.

FORGE for red-hot balls, is a place where the balls are made red-hot before they are fired off; it is constructed about five or six feet below the surface of the ground, of strong brick-work, and an iron grate, upon which the balls are laid with a large fire under them.

FORGER of false oaths, signifies either him that fraudulently makes and publishes false writings, to the prejudice of any man's right, or else the writ that lies against him who commits this offence.

Fit. N. Br. fol. 69. b. says, that a writ of deceit lies against him who commits this offence, and the penalty of it is decreed in the stat. 5 Eliz. cap. 14.

FORGERY, in *Law*, is where a person fraudulently makes and publishes false writings, to the prejudice of another man's right; and *forgery* is either at common law, or by statute, punishable by indictment, information, &c. But there can be no *forgery* where no one can be prejudiced by

by it, but the person doing it. 1 Salk. 375. *Forgery*, by common law, extends to a false and fraudulent making or altering of a deed or writing, whether it be matter of record, or any other writing, deed, or will. 3 Salk. 169. 1 Roll. abr. 65. Not only where a false deed is made, but where a fraudulent alteration is made of a true deed in a material part of it, it is *forgery*.

By a late act, an offender, *forging* or counterfeiting any deed, will, bond, bill of exchange, note, or acquittance for money, or any indenture or assignment of a bill, &c. with intent to defraud any person, or publishing such false deed, &c. to be true, knowingly, shall be guilty of felony, and suffer death as a felon; but not to work any corruption of blood, &c. Stat. 2 Geo. II. cap. 25. 7 Geo. II. cap. 22.

By an act passed in 1778, explaining the former laws on the subject of *forgery*, it is enacted, that making or forging, &c. or causing to be made or forged, &c. or assisting in making or forging, &c. any acceptance of any bill of exchange, or the number or principal sum of any accountable receipt for any note or bill, or any warrant or order for payment of money or delivery of goods, with intention to defraud any corporation, or publishing as true any such forged acceptance, &c. incur the guilt of felony, and the punishment of death, without benefit of clergy. 18 Geo. III.

FORGING, in the *Mechanic Arts*, the act of beating or hammering iron on an anvil, after having first made it red-hot in the *forge*, in order to extend it into various forms, and fashion it into works.

Iron is hammered and forged two ways; either by the force of the hand, in which there are usually several persons employed, one of them turning the iron, and hammering likewise, and the rest only hammering. Or, it is done by the force of a water-mill, which raises and works several huge hammers, beyond the force of man, under the strokes whereof the workmen present large lumps or pieces of iron, which are fashioned, at one end, by the anvils, and, at the other, by iron chains fastened to the ceiling of the forge.

This last way of *forging* is only used in the largest works, as anchors for ships, &c. which usually weigh several thousand pounds. For the lighter works, a single man suffices to hold, heat, and turn, with one hand, while he strikes with the other. Each purpose for which the work is designed, requires its proper heat. If it be too cold, it will not feel the weight of the hammer, as the smiths call it, i. e. it will not stretch or give way; and, if it be too hot, it will red-lead, i. e. it will break or crackle under the hammer.

The several heats the smiths give to their irons are, 1. A blood-red heat. 2. A white-flame heat. 3. A sparkling or scolding heat.

FORGING, in *Sea-language*, denotes the art of forcing a ship violently over a shoal, by the effort of a great quantity of sail.

FORK-RAIL, among the *Fishermen of England*, a name given to the salmon, while in the fourth year's growth, and not yet come to what they call *ASALMON*.

FORKED HEAD, *great*, in *Libbyngs*, a name given on the coast of Cornwall to the *BLENNUUS* *phoca* of Linnaeus.

FORKED HEAD, among *Hunters*, those horns of deer which bear two crochets on the top, or which have their crochets doubled.

FORLANA, in the *Italian Mops*, a sort of dance much in use among the Venetians. See *SALTARELLA*.

FORLET land, such land in the bishoprick of Hereford, as was granted or leased, *non episcopus in episcopatu siteris*, that the successor might have it for his prebend income.

But now that custom is disused, and the same lands are granted, as others, by lease; yet they still retain the name.

FORLORN, or **FORLORN-HOPS**. See *ENFAME* *predon*.

FORM, **FORMA**, in *Physics*, denotes the manner of being peculiar to each body; or that which constitutes it such a particular body, and distinguishes it from every other.

Mr. Harris uses the term *form* likewise in another sense, as an efficient animating principle; to which he supposes Ovid to refer in the first lines of his *Metamorphosis*.

*In nova fere animis mutatus diuturna forma
Ciparis*

These animating *forms* are of themselves no objects either of the ear, or of the eye; but their nature or character is understood in this, that were they never to exert their proper energies on their proper objects, the marble on which the sculptor exercises his art would remain for ever shapeless, and the harp from which the harper calls forth sounds would remain for ever silent.

Thus, also, the animating *form* of a natural body is neither its organization, nor its figure, nor any other of those inferior *forms*, which make up the system of its

visible qualities; but it is the power, which is yet able to produce, preserve, and employ these. It is the power, which first moves, and then conducts that latent process, by which the acorn becomes an oak, and the embryo becomes a man; by which digestion is performed in plants and animals, and, which departing, the body ceases to live, and its members putrefy; and by which every being produces another like itself, and every species is continued. In animals, it is that higher faculty, which by employing the organs of sense, peculiar to them as animals, distinguishes them as sensitive beings from vegetables; and it is also that more noble faculty, which by its own divine vigour, unassisted perhaps with organs, moves and denominates him a being intellectual and rational. So that Mr. Harris reckons two sorts of *forms*, those which are passive elements, and those which are efficient causes. And all of them agree in this, that they give to every being its peculiar and distinctive character; and on the whole he concludes, that *form* appears in part to be an element, and in part an efficient cause, i. e. a cause which associates the constituent elements of natural substance, and which employs them, when associated, according to their various and peculiar characters. Harris's *Phil. Arrangements*, chap. vi.

The Philosophers generally allow two principles of bodies: *matter*, as the common basis, or substratum of all; and *form*, as that which specifies and distinguishes each; and which, added to a quantity of common matter, determines or denominates it this, or that; wood, or fire, or aether, &c.

Substantial *forms* seem to have been first broached by the followers of Aristotle, who thought matter, under different moles or modifications, not sufficient to constitute different bodies; but that something substantial was necessary to set them at a greater distance: and thus introduced substantial *forms*, on the footing of souls, which specify and distinguish animals.

The considerations which the Peripatetics principally insist on, in confirmation of this doctrine, are: 1. That, without substantial *forms*, all natural things would be of the same species, nature, and essence; which is supposed to be an absurdity.

2. That every thing has its peculiar power, motion, and operation; as the magnet, e. gr. has that of attracting iron; but that this power does not flow from the matter of the body, which is only passive; nor from the accidents; and therefore that it must arise from a substantial *form*.

3. That, without substantial *forms*, there would be no generation: for a production of accidents is only an alteration.

4. That, without such *forms*, the nature of a man and of a lion would not differ.

What contributed much to their error, was the circumstances of life and death: for observing, that, as soon as the soul was departed out of a man, all motion, respiration, nutrition, &c. immediately ceased, they concluded that all those functions depended on the soul, and consequently that the soul was the *form* of the animal body or that which constituted it such: that the soul was a substance, independent of matter, nobody doubted; and hence the *forms* of other bodies were concluded equally substantial.

But to this it is answered, that though the soul be that by which a man is man, and consequently is the *form* of the human body, as human; yet it does not follow, that it is properly the *form* of this body of ours, as it is a body; nor of the several parts thereof, considered as distinct from each other.

For those several parts have their proper forms: so closely connected with their matter, that it remains inseparable therefrom, long after the soul has quitted the body: thus fish has the *form* of fish; bone of bone, &c. long after the soul is removed, as well as before.

The truth is, the body does not become incapable of performing its accustomed functions, because the soul has deserted it; but the soul takes its leave, because the body is not in a condition to perform its functions.

The ancient and modern corporeal philosophers, therefore, with the Cartesians, exclude the notion of substantial *forms*, and shew, by many arguments, that the *form* is only the modus or manner of the body it is inherent in.

And as there are only three primary modes of matter, viz. figure, *scilicet*, and motion, with two others arising therefrom, viz. magnitude, and situation, the forms of all bodies they hold to consist therein; and suppose the variations these modes are capable of, sufficient to present all the variety observable in bodies. See *MODE*.

Many varieties we actually see result from changes in these modes, which may very well pass for differences of *form*: thus, an owl differs from a needle in magnitude; a

globe from a cube in figure: and transparent glass, being pulverized, will reflect the light, and appear white; and yet all the alteration consists in the order and arrangement of the parts: when wheat is ground into flour, all the change consists in a separation of the contiguous parts; and when the flour is baked into bread, what is it but the same particles associated again in another manner? By agitating water, a froth is formed: if the agitations be increased, the particles will exhale, and form clouds; which being congregated again, return in dew, snow, hail, or rain: and the same water, by the accession of cold, might have been formed into ice. So many different bodies, endued with different qualities, and which the Peripateticks themselves allow specifically different, arise from one and the same body, by mere motion and rest!

The philosophy of substantial forms, its rise, use, and extent, are set in an excellent light by F. Malebranche. The way of thinking, that first introduced it, is this: every thing I perceive in tasting, feeling, and handling this honey and salt, is in the honey and salt; but it is certain, that the things I perceive in the honey, e. g. the colour, taste, &c. differ essentially from those I perceive in the salt: consequently there is an essential difference between the two.

Hence it follows, that they are grossly deceived, who take all the differences between those bodies to consist in the different configurations of the component parts: since the different figure is not at all essential to the different bodies: for, change the figure of the parts of the honey how you will, and even give them those of the parts of salt, yet it is honey still.

There must, therefore, be some substance added to the common matter of all bodies, to make them essentially different. And that are substantial forms hooked in; those fertile substances, which perform every thing that we see in all nature. Since then, in every natural body, there are two substances; the one common to honey, salt, and all other bodies; and the other, that which makes the honey, honey; the salt, salt; and all other bodies what they are; it follows that the first, viz. matter, having no contrary, but being indifferent to all forms, must remain without force and action, as having no occasion to defend itself.

But, for the others, viz. the substantial forms, there is a necessity of their being accompanied and invested with faculties and qualities, for their defence and subsistence. These must be always on their guard, for fear of being surprised: they are in possession of a thing, which they are to hold against numerous pretenders; and therefore they must be continually at work to fortify themselves, and extend their dominion over the neighbouring matters, and push their conquests as far as they can: were they to remain inactive, and unprepared, other forms would lay hold of them, and banish and destroy them for ever. To guard against this, they keep constant watch, and entertain mortal enmities and antipathies against those other forms, which only wait to destroy them.

If now it happens, that one form seize the matter or receptacle of another, that the form of a carcass, for instance, seize the body of a dog, it is not enough that this new form annihilate the former; but its hatred must be further gratified with the destruction of all the qualities, that took in enemy's part.

The hair of the carcass, then, must be turned white, by a creation of a new colour: its blood must become red, but of such a red, as not to be suspected in the interest of the enemy; and the whole body to be invested with qualities, truly to their new master, whom they are to defend with all the power the qualities of a carcass can have, till such time as, being overpowered, this form gives way too, in its turn, to the form of maggots, worms, &c.

But as nothing can be in perpetual war, but every thing has its place of rest, it follows, that even the fire must likewise have its centre, whither its natural levity always prompts it, that it may remain at rest, cease to burn, and even quit its heat, which it only maintains here below for its defence.

There may serve as a tale of the consequences drawn from that important principle, substantial forms; which is infinitely fertile, and furnishes every philosopher with all sorts of solutions, according to his ability, address, inclination, &c.

Forms are usually distinguished into essential and accidental.

Forms, Essential. Though the five modes above mentioned, generally taken, be adventitious; yet, to this or that body, e. g. to fire, or water, they are essential: thus, it is accidental to iron, to have this or that magnitude, figure, or situation, since it might exist in different ones; yet, to a knife, or hammer, the figure, magnitude, and

position of parts, which constitute it a hammer, or knife, are essential; and they cannot exist, or be conceived, without them.

Hence it is inferred, that, though there be no substantial forms, there are essential forms, whence the several species of bodies become what they are, and are distinguished from all others.

Forms, Accidental, are those really inherent in bodies, but in such manner as that the body may exist in all its perfection without them. Such is whiteness in a wall, heat in water; a figure of a man in wax, &c.

Form, Metaphysical, is nothing else but specific difference; as metaphysical matter is nothing else but the genus. Thus, rational is the metaphysical form of man.

Form, again, are distinguished into simple and compound. Forms, Simple, are those of simple bodies, i. e. of such as have but few properties.

Forms, Compound, are those of more compound bodies; or of such as have more properties.

Thus, e. g. if the form of a hard body be compared with the form of wood, the former may be accounted simple, and the latter complex: inasmuch as a hard body, considered only as hard, has fewer properties than wood. Absolutely speaking, however, simple forms are those of the elements, and compound, those of mixt bodies.

Some distinguish forms into natural and artificial. Forms, Natural, are those inherent in bodies, without any thing contributed thereto as the part of man. Such is the form of marble.

Forms, Artificial, are those arising from human industry. Such is that of a statue. But this distinction is useless, and does not imply any intrinsic difference in the forms themselves.

Others, again, distinguish forms into primary and secondary. Forms, Primary or universal, are those which originally belong to physical and natural body; and these, they say, are extension, figure, and organization; figure having respect to its external organization to its internal, and extension being common to both.

Forms, Secondary, are the same with sensible qualities and arise, for the most part, from the primary forms, Harris's Philos. Arrangements, p. 88.

Form of corporeity, in Ecclesiastical History. See CONCORD. Form of Corporeity, according to Averroes, and the Scotists, is that which constitutes body in the general use of body.

That there is such a thing, they prove thus: the human body is a natural body, which cannot be placed in the use of body, but by the form of corporeity: for it is either so placed by this, or by the rational soul; not by the soul, since that is spiritual; therefore by the form of corporeity. And the same may be understood of other bodies: but the later philosophers set this aside as a chimaera.

Form of a series, in Algebra. See SERIES.

Form, Sylogistic, is a just disposition, both of the terms, in respect of predicate and subject; and of the propositions, in respect of quantity and quality.

By just disposition, we mean such an one, wherein the conclusion follows duly and legitimately from the two premises, there being no form where there is no conclusion. See SYLLOGISM.

The disposition of the several terms, being, as it were, in many steps or degrees of a sylogistic form, is called the figure of the syllogism.

The disposition of the premises alone, being, as it were another degree, is called the mode of the syllogism.

Form, in Theology, denotes one of the essential parts of the sacraments, being that which gives them their sacramental nature and efficacy.

The form consists in certain words, which the priest pronounces in administering them. In some of the Sacraments, the form is deprecative: in ours it is affirmative, or indicative.

The fathers and ancient divines held, that the sacraments consisted of things and words, *res et verba*. William of Auxerre was the first, who, about the beginning of the 13th century, introduced the terms, matter and form, in lieu thereof.

Form, is also used, in a moral sense, for a manner of being, or doing a thing according to rules.

This republic has frequently changed its form of government; that is, its constitution. Patrons generally express a remission or abolition of a crime, in what form or manner forever it be committed. He was admitted doctor in form. Put your argument in form.

Form, in Law, is applied to certain established rules to be observed in proceedings or judiciary proceedings. In which sense the word stands opposed to the ground or matter in dispute, or the merits of a cause.

Contra FORMAM collationis, sacramenti, and statuti. See CONTRA.

Male & Female. See **Mono**.

Form, in Jurisprudence. is applied to the long seats or benches in the choir of churches, for the priests, canons, prebendaries, religious, &c. to sit on.

De Cange takes the name to be derived from hence, that the backs of the seats were anciently enriched with figures of painting and sculpture, called in Latin *forme & typi*. In the life of St. William of Rochdale, we meet with *forma* as signifying a seat for an ecclesiastic, or religious, in a choir; and in that of St. Lupicin, we have *formale* in the same sense. In the rule of the monastery of St. Cuthbert, the man who presides over the choir is called *primicerius, vel formatus*.

Form is also used in the same sense with **class**.

Form also denotes the external appearance or surface of a body; or the disposition of its parts, as to length, breadth, and thickness.

In which sense it coincides with figure.

Form is also said, in the *Metaphysical*, for a kind of mould wherein a thing is fashioned or wrought.

Such are the hatters' form, the paper-makers' form, &c.

Form, Matter, is a large block or piece of wood of a cylindrical figure; the top whereof being rounded, and the bottom quite flat.

Its use is, to mould or fashion the crown of the hat, after the matter thereof has been beaten and felled.

To *form a hat*, it is necessary the wool, hair, &c. be very hot, just reaching out of the copper.

Form, Paper-maker, is the frame or mould wherein the sheets are fashioned. See **PAPER**.

Form, Printer, is an assemblage of letters, words, and lines, arranged in order, and disposed, into pages, by the compositor; from which, by means of ink and a press, the printed sheets are drawn.

Every *form* is inclosed in an iron chafe, wherein it is firmly locked by a number of pieces of wood, some long and narrow, and others, in form of wedges.

There are two forms required for every sheet; one for each side; and each form consists of block- or letter-pieces, according to the volume of the book. See **PAPER**, and **PRINTING**.

Forma, in Hunting, denotes the feet of a hare, or the place and time when and where his tracks.

FORMA PAPERIS, or in FORMA PAPERIS, is when any person has a title of suit, but is so poor that he cannot dispense the usual charges of suing at law, or in equity.

In this case, upon his making oath that he is not worth 5*l.* his debt being paid, and bringing his certificate from some lawyer, that he has just cause of suit, the judge admits him to sue in *forma papeiris*; that is, without paying fees to the counsellor, attorney, or clerk. This custom has its beginning from Stat. 11 Hen. VII. cap. 12. See **DILAPIDATION**.

FORMAL, signifying that regards the *form*; or that gives the manner, or *form*.

The *formal cause*, joining itself to the material, produces the body, or compound.

The schoolmen also apply the word to any thing which has a kind of *form*, either essential or accidental, at least, in our conception.

Thus we frequently hear the philosophers talk of the *formal object* of knowledge; and of the *formal reason* of any thing; *formal unity*, &c.

FORMAL CAUSE, is defined, by certain philosophers, to be something implanted in one parcel of matter, whereby it is distinguished from all other matter.

For matter is supposed common to all bodies: consequently, that they are distinguishable from one another, does not arise from their matter, but from the *form* which is peculiar to each: hence, what is produced by such cause, is said to be *formal*.

Hence it follows, that the causality of matter and *form* is not the same; or that the component power and the actual composition, are different; contrary to the opinion of the generality of schoolmen, who, maintaining *form* to be a substance co-extended with matter, make it a real component part, as much as matter itself.

FORMAL CAUSE. See **CARTEL**.

FORMAL MATTER. See **NOTION**.

FORMAL is also used in a moral sense, importing positive, explicit, and precise.

Thus we say, a *formal agreement*, a *formal test*, *formal answer*, &c. *Formal evidence*. See **EVIDENCE**.

FORMALITER, **FORMALLY**, is variously used in the schools.

Sometimes it is understood of the subject, when a predicate is therein on account of some form: thus, white, *formally* light, diffuses light; q. d. the form inherent in this subject, viz. whiteness, is the cause why the subject diffuses the light.

FORMALLY has also place in suppositions; a word being *formally* supposed, when it is taken for the thing it was intended to signify: as, *man* is an animal.

FORMALLY, is also used in the same sense with *adequately*, and totally: thus, a syllogism *formally*, i. e. adequately taken, requires three propositions.

Sometimes it is also used for *quadrilaterally*; thus man, *formally* taken, is a reasonable animal.

FORMALLY is also used for *really*, in opposition to objectively; thus, a thing is said to be *formally* such, when it is such in the proper notion of the thing spoken of.

FORMALLY, again, is used in speaking of the manner wherein a thing is contained in another, in opposition to *virtually*, and *eminently*.

FORMALITY, the quality of a *form*, or *formula*; or that which constitutes and decomposes them such.

FORMALITY, as defined in the *philosophy*, is any manner, wherein a thing is conceived; or, a manner in any object, imparting a relation to the understanding, whereby it may be distinguished from another object.

Thus, animality and rationality are *formalities*. The Scotists make great use of *formality*, in opposition to the virtualities of the Thomists.

The Scotists hold, that the metaphysical degrees in man are to many *formalities*, really distinct from each other; as *man*, *living*, *animal*, &c. And the same they hold of the attributes of God. The Thomists, on the contrary, contend, that they are really and intrinsically the same.

FORMALITIES, in *Matters of Law*, are frequently used for the formulas themselves, or the rules prescribed for judiciary proceedings. In matters of third law, all the *formalities* must be strictly observed: in a question of the best *formality* may win the whole contention.

The term is also used for a certain order, or decorum, to be observed.

FORMATION, in *Philosophy*, &c. the act of forming, fashioning, or producing, a thing.

The formation of the chick in the egg is admirably explained by Malpighi, in an *experimental*, *De Formatione Pulli in Ovo*.

The formation of the *vegetus*, the embryo, in the womb, is a process of which we have but very dark conceptions. See **GENERATION**.

The formation of metals is effected in the earth, of *super*, or vapours, raised by the subterraneous fire; and fixed or condensed as they arrive towards the surface of the earth.

FORMATION OF MINES. See **STONE**.

FORMATION OF THE PARTS OF ANIMALS. See **CORPUS**.

FORMATRIX, or **FORMATRIX**, &c. The ancient philosophers admitted a *series*, or *formal formatrix*, whereby all bodies had their forms given them.

FORMATUM, &c. See **FORMATION**.

FORME, or **FORME**, in *Heracles*. A *crisp forme*, or *forme*, is a crisp narrow in the centre, and broad at the extremity; so called by Leigh and Morgan, though most other authors call it *paire*.

FORMED, or **FORMED**, among *Naturalists*, are such bodies, as, being either pure stone, flint, or spar, are found in the earth, so formed, as that they bear a near resemblance to the external figure of muscles, cockles, oysters, or other shells, or to plants, or animals.

Authors have been greatly divided as to their origin: the several opinions see under the articles, **FOSSIL**, **SHELL**, &c.

FORMED, &c. See **BACHELOR**.

FORMED, in *Heracles*, the same as *foet*.

FORMEDON, *formam formam*, in *Law*, a writ which lies for him who has right to lands or tenements by virtue of an entail arising from the statute of Westminster, 2. 13 Edw. I. cap. 1.

The time of limitation in a *formedon*, by Stat. 21 Jac. I. cap. 16, is twenty years; within which space of time, after his title accrues, the demandant must bring his action, or else is for ever barred.

There are three kinds, viz. *forma disjuncta*, or *formale* in the defendant; *formation in the remainder*; and *formation in the reverter*.

FORMATION in the defendant lies for the recovery of lands, &c. given to one and the heirs of his body; or to a man and his wife, and the heirs of their two bodies; or to a man and his wife, being co-heirs to the donor, in frank marriage, and afterwards alienated by the donee.

After his death, his heirs shall have this writ against the tenant or heirs.

FORMEDON in the remainder lies, where a man gives land to another for life or in tail, with the remainder to a third person in tail or in fee; and afterwards the former tenant

tenant dies without issue, and a stranger abates; then he in remainder shall have this writ.

FORFEITURE is the *reversion* lies for the donor, or his heirs (whose land is intailed to certain persons, and their issue, with condition, for want of such issue, to revert to the donor, and his heirs), against him to whom the donee alienates after the issue extinct to which it was intailed.

FORMELLA, a certain weight of about seventy pounds, mentioned in the statute of weights and measures, 51 Hen. III.

FORMER, in *Gunnery*, a round piece of wood fitted to the diameter of the bore of a gun, on which the paper, parchment, or flannel, which is to make the cartridge, is rolled before it be pulled or forced.

FORMICA, in *Zoology*. See *Ant*.

FORMICA, in *Medicine*, a species of tumid callous wart, of a blackish colour, and broad base, which appears like the flings of ants, called also *formica*.

And hence the name *formica*, which literally denotes an ant; for the like reason it is denominated by the Greeks, *μυρμηκία*.

The name *ant*, *formica*, is also given to those minute various infestances of the smallest blood-vessels, observed either in the anus, or the glans of the penis.

Some also give the appellation *ant*, or *formica*, to the military herps.

FORMICA, among *Spaniards*, the name of a disease incident to Spanish.

FORMICA, in the *ant-lion*, in *Natural History*, the name given by authors to a very remarkable species of insect, which is, in its perfect state, a winged creature, approaching to the nature of the *Libella*, or *Dragon-fly*; but in its prior state of a creeping animal, has a wonderful art and address in catching its prey. It is in this state that it is known by the name of *formica-lion*, as it chiefly feeds upon ants.

It is somewhat of the nature of the spider in its way of taking its prey, its manner of spinning, and in the figure and fineness of its body. And has, in its general figure, somewhat of the appearance of the millipede, or wood-louse; in that form he misleads it at first sight for that animal. It is of a dirty greyish colour marked with some black spots, and there are also many points, which when it is viewed with the microscope, make it resemble a hedge-hog or porcupine. Its body is composed of several rings, and has thence a wrinkled look. It has six legs; four are joined to the breast, and the other two to a long part which may be taken for its neck; its head is small and flat, and it has two remarkable horns; these are about a sixth of an inch long, and as thick as a hair, and are hard, hollow, and hooked at the end, like the claws of a cat; at the origin of each of these horns, it has a clear and bright black eye, which sees very distinctly, and gives the creature notice to escape on sight of the smallest object. Mem. Acad. Par. 1704.

He usually encamps under an old wall, that he may be sheltered from the injuries of the weather, and he always chooses a place where the soil is composed of a fine dry sand; in this he makes a pit of the shape of a funnel, or an inverted hollow cone.

When he has finished his pit, he buries himself at the bottom of it in the sand, leaving no part above ground, but the tips of his two horns, which he expands to the two sides of the pit. In this condition he lies and waits for his prey, and never comes up after it. When an ant, or any other such creature, chanced to walk over the edges of his pit, his legs throw down a little of the sand, which naturally running down to the bottom of the pit, gives the enemy notice of his prey; he then toiles up the sand which covers his head, to bury the ant, and bring him down with its returning force to the bottom; and as one attempt cannot be sufficient to prevent the ant's escape, he throws more and more sand upon him, till he by degrees brings him down to the bottom. All the endeavours of the ant to escape, when once it is within the verge of the pit, are in vain; for, as it attempts to climb, the sand runs away from under its feet, and it sinks the lower for every attempt. This motion of the sand also informs the enemy where it is, and directs him to throw up more sand in the right place, which it does till the poor ant falls to the bottom between its horns. It then plunges their points deep into the ant's body, and having sucked out all the juices of the prey, it throws out the empty skin, as far from the hole as it can. This done, it mounts up the edges of its pit, and if they have suffered any injury, repairs them with great care, and immediately buries itself again in the centre to wait for another meal.

The horns of this creature are its only organs for receiving nourishment; it never brings any animal that it has seized near to its head, but always holds it at the tip of the horn; they therefore plainly serve as syringes, to draw into its stomach the juices of the bodies of the insects it feeds on; neither is there any mouth or trunk,

Vol. II. N° 138.

or any other organ to be discovered about its head, which could serve to the purpose of eating, the head seeming only intended to throw away the sand in forming the pit. The horns of this animal being necessary to its life, nature has provided for the restoring them in case of accidents, and if cut off they are found to grow again.

When the *formica-lion* has lived a proper time in this state, it leaves its pit, and is only then drawing lines and traces on the surface of the sand; after this it builds itself under the surface, and there incloses itself in a fine web to pass its transformation into the winged state. This case is made of a sort of silk, which the creature spins in the manner of the spider, and of a quantity of the grains of sand cemented together by a glutinous humour which flows from its pores. This case, however, would be too hard and elastic for the body of the creature, and therefore it serves only for the outer covering, to defend it from injuries; the creature spinning one of pure and incomparably fine silk, of a beautiful pearly-colour within it, which covers its whole body.

When the creature has lain some time in this case, it throws off its outer skin, with the eyes, the horns, and every other part necessary to its life before, and becomes an oblong nymph, in which a careful eye may trace the form of the fly it is to become. There may be seen through its transparent covering, new eyes, new horns, wings, and all the other parts of the animal in its perfect state. This nymph makes it way about half out of the shell, and remains in this condition, but without farther life or motion, till the perfect fly makes its way out as a fly in the back; in this state it much resembles the *Libella*, or *Dragon-fly*, common about our waters. The male couples with the female in this state only, and Mr. Ponsart, to whom the world is indebted for this curious description, is of opinion that the females lay only one egg; but this is very different from the course of nature, in the other animals of the same class. Mem. Acad. Par. 1704.

The common *formica-lion* moves only backward, but Mr. Rouet has observed a species which moves forward in the common way of other animals, and makes no pit of this kind to intrap its prey, but seizes other insects by force. Philol. Trans. N° 469. p. 466.

FORMATION, a term used among *Builders*, for arching or vaulting.

FORMING is used for the act of giving being or birth to any thing.

The word is also simply used for giving the figure to any thing. The potter *forms* his vessels as he pleases. Geometry teaches how to *form* all kinds of figures.

It is also used for the producing of a thing; thus, the lineaments of the face began to be *formed*.

FORMING of a siege is the making lines of circumvallation, to fortify the camp, and disposing things for the attack of a place in *form*.

They also say, to *form* a Squadron or battalion a meaning, to range the soldiers in *form* of a Squadron, &c.

The term is also used in speaking of a body of forces, which being out of any order of Squadrons, battalions, &c. do halt, range themselves in order, and put themselves in a condition for the attack.

Forming the line, is drawing up infantry, cavalry, and artillery, into line of battle. See *LINE*.

Asper FORMING the flank. See *ANGLE*.

FORMING is also used in grammar, in speaking of certain tenses of verbs, which are made from others, by a change of certain letters.

The present tense is *formed* from the infinitive. Compound and derivative words also, and even all that have any etymology, are said to be *formed*.

FORMULA, a rule, or model, or certain terms prescribed and decreed by authority, for the form and number of an act, instrument, proceeding, or the like.

The Roman law was full of *Formulae*. The *Formulae* of Marculphus, with M. Bignon's Comment, are in great esteem.

FORMULA, in *Church-history* and *Theology*, denotes a formula, or profession of faith.

FORMULA, in *Medicine*, denotes a little form, or prescription, such as physicians direct in extemporaneous practice, in distinction from the greater forms, which are the official medicines. See *PRESCRIPTION*.

FORMULARY, a writing, containing the form or formula of an oath, declaration, attestation, or adjuration, &c. to be made on certain occasions.

There are also *formularies* of devotion, of prayers, &c. Liturgies are *formularies* of the public service in most churches.

FORNA, in *Ichthyology*, a name given by Hildegard, and others, to the trout.

FORNACALIA, or **FORNICALIA**, a fault being among the ancient Romans, in honour of the goddess Fornax, or Fornix. It was solemnized with sacrifices, performed

before the mouth of an oven, wherein they dried their corn, baked their bread, &c. The *feruitalia* were movable: the grand curio proclaimed the time of celebration every year on the twelfth of the calends of March. They were first instituted by Numa; and the *Quirinalia* were instituted for the sake of such as had not kept the *Fornicula*.

FORNAGE, *foruagium*, in our Old Writers, signifies the fee taken by a lord from his tenants, bound to bake in the lord's oven, or for a permission to use their own; this was usual in the northern parts of England. The word comes from the French *foruage* which signifies the same.

FORNICATION, *fornicatio*, the act or crime of intemperance between single persons, for, if either of the parties be married, it becomes adultery.

St. Thomas labours much to prove simple fornication contrary to the law of nature.

By the ancient law of England, the first offence herein was punished with three months imprisonment; the second was made felony, by an act in the time of the late usurpation. At present, doing public penance is the chief punishment. See **BASTARD**.

FORNICATION is sometimes used as a general term, including all kinds of offences against chastity.

Its species are, 1. *Simple fornication*, which is that committed with a prostitute. 2. *Stuprum*, that committed with persons of reputation and sobriety. 3. That committed with relations, called *incestus*. 4. That committed with married persons, called *adultery*. 5. That committed with persons consecrated to God, called *fornicatio*. 6. That committed between persons of the same sex, called *sodomia*. 7. That committed by persons on themselves, called *self-fornication*. And, 8. That committed with beasts, called *bestiality*.

FORNIX, in Anatomy, the extremity of the corpus callosum, next the cerebellum; which is separated or divided into two legs, forming a kind of arch, or *foruix*. See *Corpus callosum*.

FORPRISE, in Law, an exception, or reservation: In which sense the word is used in the statute of Exon. 14 Edw. I.

We still use it in conveyances and leases, wherein excepted and *forprius* are synonymous terms.

FORPRISE is also used for an excision: In which sense it amounts to the same with *forseipsum*.

Foruix gratum, See *foruix* *gratum* in *excusation* *propter gratiam*.

FORRAGE, or *Forage*, provision for cattle, of hay, oats, and straw; particularly in war.

Skinner derives the word from *foruix agere*, by reason they go abroad to seek *forage*; others from *foru*, which anciently signified any kind of corn or grain. Menage, from *foruagium*, of *foruagium*, or *foruagium*, which the Romans used in the same sense. Coja and Du-Cange derive it from the German *fater*, *foru-mat*; Vallius, from the German *fater*, or *foru*, is *fater*; Nicod, from *forage*, which literally signifies what we call *forage*, and figuratively, mixture of divers kinds of things; Hicks derives it from the Saxon *foru*, or the English *fater*, or the base Latin *foru*. See **FORNICE**.

In marching, encamping, &c. care must be taken, that the cavalry may find *forage*.

A ration of *forage* is the portion of hay, straw, and oats, allowed each horseman, for the subsistence of his horse one day; which is twenty pounds of hay, five of straw, and ten pounds of oats. See **RATION**.

FORRAGE-GUARD, in Military Affairs, a detachment sent out to secure the *forragers*. The *forrage-guard* is posted at all places, where the enemies parties may come to disturb the *forragers*. This guard is likewise called the *covering party*, and marches generally the night before the *forragers*, that they may be posted in the morning before the *forragers* come. The guard consists both of horse and foot, and must stay at their post till the *forragers* be all come off the ground.

FORSSES, *catulape*, a term used in Westmoreland for water-falls.

FORSKHOUEA, in Botany, a genus of the *diandria pentagyna* class, with a five-toothed calyx extending beyond the corolla, two spatulate petals, no pericarpium, and five seeds connected by a woolly down. There is one species.

FORSTAL, } See **FORSTALL**.

FORSTALLING, } See **FORSTALLING**.

FORT, a little castle or fortress, or a place of small extent, fortified by art, or nature, or both.

A *fort* is a work encompassed round with a moat, rampart, and parapet, to secure some high ground, or passage of a river; to make good an advantageous post; to fortify the lines and quarters of a siege.

FORT, *feld*, otherwise called *Fortin* or *Fortlet*, and sometimes *Semois*, is a small fort, built in haste, for the defence of a pass or post; but particularly constructed for the defence of a camp in the time of a siege, where the

principal quarters are usually joined, or made to communicate with each other, by lines defended by fortins and redoubts. Their figure and size are various, according to the nature of the situation, and the importance of the service for which they are intended. Some are fortified with bastions, and some with demi-bastions. A *fort* differs from a *CITADELLE*, as this last is erected to command and guard some town; and from a *redoubt*, as it is closed on all sides; whereas a *redoubt* is open on one side.

Fort is most commonly made square (see *Tab. Fortification*, fig. 5.) especially when the pass they are to guard is of any consequence, or the place may easily be approached; the sides of this figure are a hundred toises, the perpendicular ten, and the faces twenty-five; the ditch about this *fort* may be from ten to twelve toises; the parapet is to be made of turf, and fraised; and the ditch palissaded when dry. There may be made a covert-way about this *fort*, or else a row of palisades might be placed on the outside of the ditch.

A *square fort* may be fortified in the following manner: having inscribed the square in a circle, divide each of its sides, A B, B D, &c. into two equal parts in the points F, M, &c. from the centre E draw an indefinite line E F; from the centre draw also the lines E A, E B, E D, E C, to the angles of the square; divide the side A B into eight equal parts, and set off one of these parts from F to G, and from G draw the lines of defence A G, B G; divide another side of the square into seven equal parts, and set off two of those parts from A to K, and from B to L, which will be the faces of the bastions, take the distance K L in your compasses, and set it off on the lines of defence from K to H, and from L to I, and draw H I, which will be the curtain, and the lines K I, L H, will be the flanks. Or, it may be otherwise fortified thus: let the side A A (fig. 6.) be a hundred and thirty fathoms; the demi-gorge A B, twenty five fathoms; and with the compasses opened to the length of the pinched line B C B, which is the diagonal of two sides, from each of which there has been taken twenty-five fathoms, upon the extremity opposed to the angle which they form, describe two arcs above the angle of the figure, after nearly making use of the points B for centres; then draw lines from the points of intersection of the arcs D, to the point which served for centres B, upon which points B, raise the flanks B E perpendicular to the opposed lines of defence B D.

Fort point, or *Fort*, See **PAINE**.

Fort royal is a *fort*, whose line of defence is at least twenty-six fathoms long.

Fort, *star*, is a fence or redoubt, constituted by re-entering and salient angles, having commonly from five to eight points, and the sides flanking each other.

To describe a *star-fort*. Describe a hexagon A B C D E F (fig. 7.) divide one of its sides into four equal parts; and on the centre of this side raise the perpendicular D A equal to one fourth of the side B C. From the point A draw the faces A C and A E, and let the same operations be performed with respect to the other sides of the hexagon.

Fort is sometimes made *triangular*, only with half bastions, as in fig. 8. This, as well as the square and pentagonal *fort*, (fig. 9. and 10.) may be described in the following manner. Parallel to the inner figure, whether it be a triangle, square, or pentagon, whose side A B may be supposed about eighteen yards, describe an outward figure at the distance of about four or five yards from it, or farther, if necessary, whose sides are E D, E F, &c. Divide each side, as E D, E F, &c. into three equal parts, one of which is E I, F L, &c. and in these lines prolonged, take D G, E H, &c. each equal to one of those three parts. From the points G, H, &c. thus found, draw the lines of defence to the angles of the outward figure, as H D, &c. and from the points I, L, &c. draw the flanks I K, L M, &c. perpendicular to the lines E D, E F, meeting the lines of defence in K, M, &c. Or the flanks may be drawn, by continuing the side D I towards K, and taking I P equal to twice I E; from P as a centre, with the radius P K, cut the line of defence in K, and draw the flank I K. Then to each face H K, flank K I, and curtain I G, make a parapet of about seven feet thick, or more if necessary, expressed in the figures, by drawing lines at that distance on the inside of the several parts. Leave a proper beam of about four or five feet broad, and a ditch about five or six yards wide, whose outer line or counter-scarp is to be parallel to the faces and curtains only. A *fort* thus constructed is more capable of defence than one without flanks; for the curtain I G is defended by the flank I K; and the face H K has some defence from the part D G. In the construction of triangular *forts*, (fig. 11.) instead of making half bastions at the angles, whole ones are placed in the middle of the sides. The gorges of these bastions may be from twenty to twenty-four toises, when

the sides are from a hundred to a hundred and twenty; the flanks are perpendicular to the sides, from ten to twelve toises long, and the capitals from twenty to twenty-four. If the sides happen to be greater or less, the parts of the bastions are likewise made greater or less in proportion; the ditch round this fort may be ten or twelve toises wide. The ramparts and parapets of these works are commonly made of turf, and the outside of the parapet fringed. Forts are often made of various figures, regular or irregular, and sometimes in the form of a semi-circle, especially when they are situated near a river, sea, or at the entrance of a harbour, by which figure they are able to fire at the ships on all sides. When a fort is to be built on a neck of land, formed by the confluence of two rivers, or in the windings of a river, in order to prevent an enemy from transporting any thing by water, or to prevent their ships passing that way, the figure of the fort must be adapted to the situation, in such a manner, that there may be no place for landing troops out of the reach of the fire of some work or other; and the side next to the land should always be better fortified than the other parts near the river, as being more liable to an attack. There are two principal errors committed in the construction of forts near the sea, or navigable rivers, which should be carefully guarded against; the one is, that of making the parapet too low, so that persons behind it may be fired upon from the round top of a mast, by which the gunners are obliged to abandon their guns, and to save themselves by flight: to remedy this inconvenience, the parapet should be nine or ten feet high, and the batteries may be covered above by making an arch over every piece left open behind to let out the smoke, or with planks, like sheds, over which may be scattered earth or dung about a foot and half thick, to prevent the wind from taking fire. The other fault is, leaving forts or batteries open behind, or very little fortified towards the land, so that the enemy may land men in the dark and surprise them, by which the guns placed in them become not only useless, but serve rather to destroy them. A fort, or battery, therefore, should be fortified all round with a good rampart and ditch, at least, or with an addition of outworks, if the place is of any importance; the rampart should be fringed, and the ditch have a row of palisades planted in the middle of it, if it be dry. In the construction of all forts, it should be remembered, that the figure of fewell sides and bastions, that can probably answer the proposed defence, is always to be preferred; as works on such a plan are sooner executed, and with less expence; besides, fewer troops will serve, and they are more readily brought together in case of necessity.

FORTAMENTE, in the *Italian Music*, the same with **FORTE**.

FORTE, in the *Italian Music*, directs to play strong and loud.

FORTE FORTE, or **F. F.** signifies a degree louder or stronger than *forte*.

FORTE, *pin*, the same as *forte fine*.

FORTERESSE, **FORTRESS**, or **FORTRESS**, a general name for all **FORTIFIED PLACES**, whether made by nature or art. Such are fortified towns, castles, citadels, forts, towers, redoubts, fortresses, &c.

FORTIFICATION, called also *military architecture*, is the art of fortifying or strengthening a place, by making works around the same, to render it capable of being defended by a small force, against the attacks of a more numerous enemy.

Some authors go back to the beginning of the world, for the author and origin of military architecture. According to them, God himself was the first engineer, and Paradise, or the garden of Eden, was the first fortress. Cain improved on the hint, in building the first city, Gen. ix. 17. After him came Nimrod, Gen. x. 10. Then Semiramis, as *Polydore relates*. Strabonem lib. viii. cap. 27. The Canaanites, Num. xiii. 19. Deut. i. 28. David, 2 Sam. v. 9. Solomon, 2 Chron. viii. 4. Rehoboam his son, 2 Chron. xi. 5. and the other kings of Judah and Israel, and at length the Greeks and Romans. Vitruvius, lib. x. cap. ult. and lib. i. cap. 3.

Such is the series of those who fortified places; to which might be added Pharaoh, the persecutor of the Israelites, who built the cities of Pithom and Rameses, Exod. i. 11. The progress of fortification, founded first in necessity, has been, like that of other important and useful arts, gradual. When villages and towns were first formed, it was found necessary, for the common safety, to encompass them with walls and ditches, in order to prevent all violence and sudden surprisings from their neighbours; when offensive weapons were invented, walls were made with loop-holes at proper distances, in order to screen the defenders against the arrows of the assailants; but finding, that as soon as the enemy got close to the walls, they could from no part be discovered or repulsed, they

added square towers at proper distances from each other, so that every part of the wall might be defended by the adjacent side of the towers. However, this manner of inclosing towns was found to be imperfect, because there remained still one of the faces of the towers which fronted the field, that could not be seen from any other part, and, therefore, could not be defended. To remedy this, they made the towers round instead of square, imagining this figure to be the strongest for resisting the battering engines, and likewise to be better defended from the other parts of the wall. Nevertheless, part of these towers remained unseen, and incapable of being defended, which made them change them again into squares as before; but, instead of presenting a face to the field as formerly, they presented an angle; and thus they obtained such a disposition of their works, that no part could be attacked without being seen or defended by some other part.

But how ancient soever the fortification of cities with walls, towers &c. may be, the name fortification, and the art now understood thereby, are of no very old standing.

These have had their rise since the invention of cannons; the terrible effects whereof rendered it necessary to change the structure of the ancient walls, and to add so many things thereto, that those changes were thought enough to constitute a new art, which was called fortification, on account of the strength it afforded those cities, to defend them against an enemy.

The period, in which the modern practice of military architecture may be supposed to have taken its rise, was that in which the old circular towers were first converted into **BASTIONS**, about the year 1500.

The first authors who have written of fortification, considered as a particular formed art, are La Trielle, Alphonse, Marchi, Pafino, Ramelli, Carcano, and Speckle, who, as Mr. Robins says, was one of the greatest geniuses that has applied to this art. He was architect of the city of Stralsburgh, and died in the year 1589. He published a treatise of fortification in German, which was reprinted at Leipzig in 1736. Robins's Math. Tracts, vol. i. preface, p. 9.

After them Errard, engineer to Henry the Great of France; Stevinus, engineer to the prince of Orange; Marolois, the chevalier de Ville, Lorini, Coehorn, the count de Pagan, and the marshal de Vauban; which last two noble authors have contributed greatly to the perfection of the art. To whom we may add Scheiter, Mallet, Belidor, Blondel, Muller, &c.

From the idea and office of fortification, some general fundamental rules or axioms may be drawn; as,

1. That the manner of fortifying should be accommodated to that of attacking; so that no one manner can be assured always to hold, unless it be assured the manner of besieging be incapable of being altered; and that to judge of the perfection of a fortification, the method of besieging at the time when it was built must be considered.

2. All the parts of a fortification should be able to resist the most forcible machine used in besieging, and they should be equally strong on all sides.

3. A fortification should be so contrived, as that it may be defended with as few men as possible; which consideration, when well attended to, saves a vast deal of expence.

4. That the defendants may be in the better condition, they must not be exposed to the enemy's guns and mortars; but the aggressors must be exposed to theirs.

Hence, 5. All the parts of a fortification should be so disposed, as that they may defend each other: in order to this, every part there is to be flanked, i. e. capable of being seen and defended from some other; so that there be no place where an enemy can lodge himself, either unseen, or under shelter.

6. All the champaign around must lie open to the defendants; so that no hills or eminence must be allowed, behind which the enemy might shelter himself from the guns of the fortification; or from which he might annoy them with his own.

The fortification, then, is to command all the place round about; consequently the out-works must all be lower than the body of the place.

7. No line of defence is to be above point-blank musquet-shot, which is from one hundred and twenty to one hundred and fifty fathom.

8. The acuter the angle at the centre, the stronger is the place; as consisting of the more sides, and consequently more defensible.

9. All the defences should be as nearly direct as possible. Such are the general laws and views of fortification; the particular ones, respecting each several work or member thereof, will be delivered under their proper articles.

See BASTION, and FORTIFIED PLACE.
FORTIFICATION, the art of, may be distinguished into two parts, viz the *elementary or theoretical*, and *practical*.

FORTI-

FORTIFICATION, elementary or theoretical, consists in tracing the plans and profiles of a *fortification* on paper, with scales and compasses; and in examining the systems proposed by different authors, in order to discover their advantages and disadvantages.

FORTIFICATION, practical, consists in forming a project of a *fortification* according to the nature of the ground, and other necessary circumstances, tracing it on the ground, and executing the project, together with all the military buildings, such as magazines, store-houses, bridges, &c.

FORTIFICATION again is either *offensive* or *defensive*. *Offensive fortification* is the same with the *attack* of a place, and is the art of making and conducting all the different works in a *siege*, in order to gain possession of the place.

FORTIFICATION, defensive, or DEFFENCE, is the art of defending a town that is besieged, with all the advantages which the *fortification* of it will admit.

FORTIFICATION is also used for the place *fortified*; or the several works raised to defend and flank it, and keep off the enemy.

All *fortifications* consist of lines and angles, which have various names, according to their various offices.

The principal angles are those of the *entrance*, the *flanking angle*, *flank angle*, *angle of the square*, &c.

The principal lines are those of *circumvallation*, of *contravallation*, of the *capital*, &c. See each in its place.

Fortifications are divided into *regular*, and *irregular*, and again into *durable* and *temporary*.

FORTIFICATION, regular, is that wherein the bastions are all equal; or that which is built in a regular polygon, the sides and angles whereof are generally about a misapprehension from each other.

In a *regular fortification*, the parts being all equal, have the advantage of being equally defensible; so that there are no weak places.

FORTIFICATION, irregular, is that wherein the bastions are unequal, and unlike; or the sides and angles not all equal, and equidistant.

In an *irregular fortification*, the defence and strength being unequal, there is a necessity for reducing the irregular figure, at least as nearly as possible, to a regular one; i. e. instead of inscribing it in a circle, it should be inscribed in an oval, so that one half may be similar and equal to the other half.

And as the irregularity of a figure depends on the quantity of angles and sides; the irregularity of a *fortification* arises either from the angles being too small, or the sides being too long, or too short.

Consequently an irregular figure being proposed to be fortified; all the angles, with the quantity of the sides, must be found, to be able to judge how it is to be fortified. See Tab. VI. *Fortification*, fig. 30, which represents a *fortification* inscribed in an oval.

In this case the sides CD, GH, on the flat parts, are stronger than the sides AB, EF, on the narrow parts, supposing all the exterior sides equal, and the place equally fortified. When the angles BCD, CDE of the polygon are very great, and the besieger comes within a small distance of the works, he cannot approach nearer, without being seen in front, except by a direct sap, with traverses; and as this way of approaching presents but a small front, the besieged, who have a much larger, may oppose with peculiar advantage; whereas, if the angles HAB, ABC of the polygon, are very small, the besiegers may carry their approaches to the counterescarp itself, and have always a larger front than the besieged; and, as the besiegers must extend their approaches to three fronts, whether they are small or large, the work of the approaches before the front BCDE will be to the work before the front HABC, as the line BE, is to the line HC, nearly, i. e. as the greater axis of the oval is to the less; and therefore the front CD, on the flat side, is stronger than the front AB, on the narrow side; consequently, the longer CD is, so that the lines of defence are within the reach of musket-shot, and the angles BCD, CDE, are the same, the stronger will the front be; since the works become more spacious, hold more troops to defend them, and the besiegers are obliged to extend their trenches farther. Moreover, the greater the angles of the polygon BCD, CDE are, the exterior sides being the same, the stronger will be the front CD; because the length of the line BE increases, and the extent of the besiegers approaches in proportion; and, therefore, the strength of a *fortification* increases in proportion to the number and length of its sides; so that a dodecagon is stronger than an octagon, when the length of their sides is the same. However, as it is found difficult to inscribe a polygon in an ellipse or oval, the following more easy method will answer the purpose. Reduce the spot of ground to be fortified to the figure ACEG (fig. 30) and draw BE, AF, parallel to each

other; draw CH, DG, perpendicular to these lines, and at equal distance from the points B and E, and let their interval be equal to that of the lines BE and AF; then draw DG, CH, parallel to AF and BE, and equally distant from them; and from their intersections C, D, G, H, with DG, CH, as centres, describe arcs, with a radius equal to CD or GH, so as to intersect the lines AF, BE, in A, B, E, F; join the points A, B, E, F, and ABCDEFGH will be an oblong polygon, having one half similar and equal to the other half. If a hexagon be to be described, instead of drawing the two lines CH, DG, one will be sufficient; in a decagon there must be three, and four in a dodecagon. If the sides cannot easily be made equal, then the sides AB, EF, on the narrowest part of the polygon, should be the longest, because it is the weakest. But when the figure cannot in any respect be made regular, the strength of each side must be estimated according to the works a besieger is obliged to make in the attack, and according to the obstacles he meets with in his approaches. *Muller's Elements of Fort.* p. 126, &c.

FORTIFICATION, marine, is sometimes used by way of distinction from *land fortification*, and denotes the art of raising works fit for the defence of a harbour against the attacks of any kind of shipping; but the works proper for this purpose depend in a great measure on the principles employed in the *fortification* of towns. However, attention should be given to the situation of roads or harbours in contriving works for their defence; e. g. when a town lies open to the sea, on a curved, or fruit bold shore, and has before it a sufficient depth of water and good anchorage, the ships, in this situation, may be well defended by forts built near the water's edge on each side of the anchoring place, so contrived as to have two or three batteries, one higher than the other, and furnished with a sufficient number of cannon, carrying shot from twenty-four to forty-eight pounds. A town, in this situation, may be defended by a rampart, or wall, well flanked, built along the shore, beside the *fortifications* on the land side. The works along the shore should be carried to near to the water's edge, that troops, attempting to land under the cannon of a fleet, might not find ground on which to intrench themselves. Further, when a harbour, being a bay, has a shoal or small island lying before its entrance, a strong fort should be built upon the island, in a place where it can command the entrance on both sides, if the island be not too large; otherwise two or more forts should be erected in such places as may command the avenues to the bay; other forts should also be raised on the most convenient points of land, forming the mouth of the bay. Again, when the harbour is in a bay, whose points, forming the entrance, stretch into the sea, and approach one another within cannon-shot; such a harbour may be fortified by building on both sides of its entrance one or more forts; and, if possible, a fort should also be built within the harbour's mouth in such a manner, that its cannon can rake the shipping fore and aft as they come in.

When a harbour is formed by a cluster of islands, it is easily fortified, if the channel between the islands is not too wide for the command of cannon from one or both shores; but if it be too wide, the shipping that rides there must be defended from the batteries on the shore. When the harbour lies in an inlet, or river, some miles above its mouth, a fort built at each point of the entrance, when the passage lies straight, and can be commanded from side to side, and two others between them and the harbour, but not directly opposite, unless the breadth of the channel require it, will be a proper fortification for the shipping in such a harbour; and if the channel or river is winding, the forts should be built where they can command a reach at least, or be so placed at the head, as to command two adjacent reaches. See *FOURTS*, and *Robertson's Treat. of Marine Fort.* part ii. c. 2. For the *fortification* of harbours by booms, see *DOORS*.

FORTIFICATION, durable, is that built with design to remain a standing shelter for ages. Such are the usual *fortifications* of cities, frontier places, &c.

FORTIFICATION, temporary, is that erected on some emergent occasion, and only for a little time.

Such are field-works, cast up for the seizing and maintaining a post, or passage; those about camps, &c. as circumvallations, contravallations, redoubts, trenches, batteries, &c.

The methods of *fortifying*, that have been invented, are various; and new methods continue still to be proposed. We shall be a subject some of the principal, and of those which chiefly obtain through Europe, such as those of Coehorn, Pagan, Vauban, Schreiter, &c. from which all the rest are easily conceived.

FORTIFICATION, offensive is the Dutch method, or the system of Alaric, is that which, making the flank perpendicular

dicular to the curtain, makes the flank the folduple of the face, and subtriple of the curtain; and the angle of the bastion equal either to two thirds of the angle of the polygon or to half thereof, with the addition of fifteen or twenty degrees, to make it equal to a right angle.

Freitach determines the quantity of the flank in a square to be six; in a pentagon, seven; in a hexagon, eight; in a heptagon, nine; in an octagon, ten; in a decagon, eleven; and in all other figures, twelve Rhinland perches; consequently the face twenty-four, and the curtain thirty-six perches.

To draw the profile of a fortification after the Dutch manner: divide the side of the inner polygon, GH, (Tab. Fortification, fig. 1.) into five equal parts; the demi-gorge AH is to contain one of them; and the capital HC, two. Then divide the curtain EA into four parts; and make the flank AB one.

This is Freitach's method. Marolois's method of fortifying a hexagon is represented in fig. 12. Draw an indefinite right line AB; at the point A make the angle BAO equal to sixty degrees; and as the flanked angle of the hexagon, according to Marolois, is 80° , the half flanked angle will be 40° ; and let the diminished angle BAD be 20° . In AD take AE=48 toises; and from E let fall on AB the perpendicular EN, and for the flank-bray lay down 64 toises from N to I, and 72 for the length of the curtain. Take IB=AN, and at I erect a perpendicular IL=NE; and drawing the line LB, this will be the face of the demi-bastion opposite to AE. Draw OB, which makes an angle ABO of 60° , with AB. At the point E, and with NE produced, make the angle BEF= 55° , the line EF, forming this angle, will cut OA in a point F, from which draw FM parallel to AB. Produce the perpendiculars NE, IL, to the line FM, and you will have EG and LH for the flanks of the demi-bastions, and GH will be the curtain. If a circle be described on the centre O, with the radius OA, or AB, and a hexagon inscribed in it, and each side of the hexagon be fortified in the same manner, the work will be finished; and all the measures may be preferred on the front AB. We may observe, that Marolois makes the flanked angle of his square 60° , of the pentagon 72° , of the hexagon 80° , of the heptagon 85° , and of the octagon and other polygons 90° .

FORTIFICATION, according to De Ville's, or the French method. In this method the flanked angle is always right, and the flank is equal to the demi-gorge, and perpendicular to the curtain, and the lines of defence are subangles. Let AB (fig. 13) be the side of a hexagon, and divided into six equal parts: take AC and BD equal respectively to one of these parts for the demi-gorges of the bastions of the front AB; at the points C and D erect the perpendiculars CG and DH, each equal to AC or BD; these will be the flanks of the demi-bastions of the front AB. Draw the radii OA and OB, and produce them indefinitely beyond A and B; on OA produced, let fall a perpendicular IQ, from the point I; make QM=QI, and draw MI, which will be the face of the demi-bastion MLC. In the same manner the face HN of the other demi-bastion may be determined; and if the same operations are performed with regard to the other sides of the polygon, the fortification will be finished. In order to cover the flank HD with an orillon, it is divided into three equal parts; GD is taken equal to one of these parts, and through the line GN is drawn to M, in which GK is taken equal to GD. Then the face NH is produced to meet the line MG in the point R; and on this point, as a centre, with the radius RK, an arc is described, which will intersect the face NH produced, in L. Draw the line KI, and upon this let the orillon be constructed, by erecting an indefinite perpendicular on LN, at the point I, within the bastion, and another on the middle of IK towards the bastion, which perpendiculars will intersect, and the point of their intersection will give the centre of the orillon; and if the compass be opened to I or K, the arc of the orillon may be described. For a second flank, KG is produced from G to P, and FE is drawn parallel to GD.

FORTIFICATION, according to De Sardi, or the Italian method. This author allows 800 geometric Rhinland feet, or about 130 toises, to the side of his hexagon; which he divides into sixteen equal parts, three of which parts he assumes for the demi-gorge; he makes the flank perpendicular to the curtain, and equal to the demi-gorge. He divides the curtain into eight equal parts, one of which is the second flank; and through the extremity of this part, and that of the flank, he draws the face of the bastion indefinitely; and he performs the same operation with regard to the other side of the polygon; and the intersection of the faces gives the flanked angle of the bastion; and he covers his flank with an orillon or epaulement.

FORTIFICATION, according to the Spanish method. The Spanish method is the same with that of De Ville, only omitting the second flanks, and making the flanked angle obtuse. In fortifying a regular polygon, they divide the side into six equal parts; they make the demi-gorge equal to one of these parts, the flank perpendicular to the curtain, and equal to the demi-gorge, and the faces are drawn from the angle of the flank, and the extremity of the flank, and their concurrence gives the flanked angle of the bastion.

FORTIFICATION, according to the improved rules. This method is described in different Italian authors, and particularly to De Marchi; and is explained in a book of fortification of Boudin the Jesuit, printed in 1655. Let any regular polygon, e. g. a hexagon, be inscribed in a circle (fig. 14.) Let each of its sides, AB, AC, be 160 toises; divide AB into eight equal parts, and let the demi-gorge of the bastion, laid on from A and B, be equal to one of these parts. At the points D and E, which terminate the demi-gorge, erect the indefinite perpendiculars DK, EL, for the flanks of the demi-bastions at A and B. Take DF and GE, each equal to a fourth part of AB, and at the points F and G, erect the perpendiculars FH, GI, equal to the eighth part of AB, and draw the curtain HI, through the points I, and F draw the line IM, terminated in M, which line will cut the perpendicular DK in K, and DK will be the flank of the demi-bastion A, KM the face, and HF the double flank of the front AB. In the same manner the other demi-bastion may be constructed in B, and by similar operations on the other side of the polygon, the work may be completed. This method derives its name from the disposition of the flank, belonging to each front.

FORTIFICATION, according to M. Foulon's first method. This method is divided into little, mean, and great; the little is chiefly used in the construction of circles, and is commonly formed of pentagons; the mean is that of all sorts of towns, from a hexagon upwards to any number of sides; and the great only in particular cases, chiefly of irregular fortification. The construction of the mean, which is the most useful, is as follows: describe a circle with any radius AO (fig. 15. N^o 2.) and in this circle inscribe a polygon of as many sides as the fortification is designed to have front; e. g. a hexagon. Bisection AB, one of the sides; which M. Varian always supposes to be 180 toises, in C, and at this point C erect a perpendicular, CD, towards the centre of the polygon; when the polygon is a square, CD must be one eighth of the side AB; when it is a pentagon, one seventh; but when it is a hexagon, or any other polygon of a greater number of sides, CD will be one sixth of the side. In this case, then, make CD=20 toises, and through D draw the indefinite lines ADG, BDE, in which take AE and BH, each equal to 3/5 of AB, or 36 toises, neglecting the fractions. On E, as a centre, describe an arc through the point H, meeting AB in G; and on H, as a centre, describe an arc through the point E, meeting BD in F; on F, make each of the lines EG, HF, equal to the distance EH; then the lines joining the points A, E, F, G, H, B, will be the principal or outline of the front. And if the same construction be performed on the other sides of the polygon, we shall have the outline of the whole fortification. If with a radius of 20 toises, there be described circular arcs, from the angular points B, A, M, T, and lines be drawn from the opposite angles E, H, &c. so as to touch their arcs, their parts a, b, &c. together with their arcs, will represent the outline of the ditch. In this figure, the part FEALN is called the bastion, AE and AL are the faces of the bastion, EF and LN are the flanks, FG the curtain, FN the gorge of the bastion, AG and BE the lines of defence, AB the exterior side of the polygon, CD the perpendicular; any line which divides a work into two equal parts is called the CAPITAL of that work, &c. the COUNTERSCARP of the ditch, A and M the FLANKED ANGLE, H, E, F, L, the angles of the shoulder or shoulder, G, F, and N, the angles of the flank; any angle whose point turns from the place is called a SALIENT angle, such as A, M, and any angle whose point turns towards the place, is called a RE-ENTRANT angle, such as B, F, and N. If two lines be drawn parallel to the principal or outline, the one at the distance of three toises, and the other at the distance of eight toises from it, the space so inclosed between the principal one, and that farthest distant, is called the RAMPART; and the space so contained between the principal line, and that next to it, and which is generally flanked black, is called the PARAPET; within four feet of the parapet there is drawn a fine line, which expresses a step, called BANQUETTE. All works have a parapet of three toises thick, and a rampart of eight to ten, besides their slopes. The rampart is elevated more or less above the level of the place.

from ten to twenty feet, according to the nature of the ground, and the particular construction of the engineer. This parapet is a part of the rampart, elevated from six to seven feet and a half above the rest, in order to cover the troops that are drawn up there from the fire of the enemy in a siege; and the banquettes are two or three feet higher than the rampart, or about five feet lower than the parapet; so that when the troops stand upon it, they may just be able to fire over the parapet. The body of the place is that which is contained within the first rampart; and all the works which are constructed beyond the ditch, before the body of the place, are called out-works.

The following table exhibits the proportional dimensions of the several parts in the little, mean, and great fortification of M. Vauban. In the first horizontal column are the numbers expressing the lengths of the exterior sides from 80 to 200; in the second, the perpendiculars answering to these sides; in the third, the lengths of the faces of the bastions; and in the fourth, the lengths of the capitals of the ravelins.

TABLE

	80	100	120	140	160	180	200
Side of the tower	10	12	14	16	18	20	22
Perpendicular	10	12	14	16	18	20	22
Face of the bastion	10	12	14	16	18	20	22
Capital of the ravelin	10	12	14	16	18	20	22

The principal works that are now used in the construction of fortified places, beside those that have been already mentioned, are ARROWS, COVERT-WAYS, COUNTERGARDS, CROWN-WORKS, DITCHES, raised FLANKS, GLACIS, HALF-MOONS, HORN-WORKS, LUNETTES, ORILLONS, RAVELINS, detached REDOUTES, TENAILLES, and TENAILLONS.

FORTIFICATION, according to M. Vauban's second method, with tower-bastions, called the system of Landau, because the city of Landau is fortified after this manner. Let AB (fig. 16.) be the interior side of a hexagon, equal to 120 toises; draw AC, BD , from the centre, through the extremities of the side; set off 6 toises from A to r , and from B to s ; through the points r and s , draw lines at right angles to AB ; from r set off six toises to t outwards, and four from t to d inwards; and from the points r and s draw perpendiculars rr', ss' to the capital AC ; then if $r'E$ is made equal to rs , the point E will be the fallant angle of the tower-bastion, and $E'F$ half the tower. If in the capitals, there be taken, from the fallant angles of the tower-bastions, the distances EC, FD , each of forty toises, the points C and D will be the fallant angles of the counterguards before the towers. From the points C and D draw the lines of defence Cc, Dd , to the points where the flanks of the towers cut the curtain; on which set off fifty-six toises for the faces of the counterguards; the flanks are found as in the first method, and likewise the tenailles. The ditch before the fallant angles of the towers is six toises, and its counterescarp drawn to the extremities of the flanks of the counterguards; the right line which joins the ends of both flanks will determine the inside of the tenailles. The ditch before the counterguards is twelve toises at the fallant angles, and the counterescarp is drawn to the opposite angles in the same manner as in the first method. The capital of the ravelin is forty-five toises, its faces, when produced, terminate on those of the counterguards, within ten toises of the shoulders; ten toises are cut off from the faces by the flanks, which are parallel to the capital as usual. The ditch before the ravelin is ten toises; the covert-way faces, the semi-gorges of the places of arms twelve, the faces sixteen, and the glacis twenty. See fig. 17.

FORTIFICATION, according to M. Vauban's third method, or that of New Brich. This method is applied to an octagon, whose exterior side AB (Tab. II. fig. 18.) is 180 toises, the perpendicular CD , 30; the faces AK, BL , of the counterguards, 60; the flanks LN, KM , are found by setting off 22 toises, as chords to the arcs described from the opposite shoulders as centres. From the extremities of the flanks a line is drawn, which will be parallel to the exterior side AB , meeting the capitals AE, BF of the counterguards at G and H , which line will terminate the inside of the tenaille, and also the fallant angles, G, H , of the tower-bastions. If EF be drawn parallel to GH , and at nine toises distant from it, the intersections E, F , with the capitals of the counterguards, will be the centres of the towers; from which set off seven toises from E to a , and F to b , for the semi-gorges, and draw the flanks ac, bd , from the extremities of these semi-gorges, perpendicular to the line EF ; these flanks are four toises inwards from a to r , and b to s , and five outwards from r to t , and s to u ; the faces CG, HD , are

drawn from the points b and s to G and H , and the lines joining the inside of the flanks, at the end of four toises, will complete the towers. The ditch is six toises before the fallant angle of the towers, and its counterescarp meets the line GH , within ten toises of the extremities M, N , of the flanks of the counterguards. If from the point a , when the line EF intersects the perpendicular CD produced, five toises be set off to the point r , and the lines of defence are drawn from the extremities of the semi-gorges a and b of the towers through this point r ; then the flanks of the counterguards produced will determine the little flanks gs , and ht , of the infide rampart, and the extremities of these little flanks being joined, will give the curtain between them. The great ditch before the counterguards is fifteen toises, and its counterescarp parallel to the faces; the capital of the ravelin is fifty-five toises, and that of the redoubt within it twenty-three; the faces of the ravelin are drawn to the faces of the counterguard within fifteen toises from the shoulders, and those of the redoubt parallel to these; twelve toises are cut off from the faces of the ravelin, and six from those of the redoubt, by the flanks which are parallel to the capital; the ditch before the ravelin is twelve toises, and that before the redoubt six; the covert-way and glacis are the same as in the second method. The parapets of the counterguards, on both sides of the fallant angles, are raised four feet higher for the space of twenty feet above the rest, in order to prevent the enemies of the picket batteries. See fig. 19.

Mr. Muller has made several remarks on the three methods of M. Vauban above recited. With regard to the first he observes, that it is simple, easily constructed, and takes up but little ground, about once and a half more ground than the buildings. It is guarded from surprise by its stone revetment, requires only few men to defend it, and with the addition of some outworks, as counterguards before the bastions, and lunettes or tenailles to cover the ravelins, furnishes a good defence. However, his flanks are too small; his raised flanks on circular arcs of 60° are needless, since the flanks made upon their chords will contain as many guns, and resist better than the curved flank; his capital ditch is too wide, the faces of the ravelins, instead of terminating on the shoulders of the bastions, should terminate three or four toises beyond them; the semi-gorges of the boulet, instead of being fifteen toises, should, in Mr. Muller's opinion, be but eight or ten at most; one of the faces of the lunettes should be perpendicular to the face of the ravelin, and the other to that of the bastion, in order to be defended in a direct manner; instead of the counterguards before the ravelin, which are seldom made, he recommends a redoubt within it, as less expensive, and answering the same purpose. All tenailles and counterguards should have retrenchments.

The second method, he observes, is designed for fortifying an old town already inclosed by a rampart; on which account M. Vauban begins within, and fortifies outwards, contrary to his other methods; the tower bastions are joined to the old wall, and have underneath a magazine in the form of a cross, round which are casemates, or cellars, to hold both men and guns; those in the flanks have each an embrasure, which opens into the ditch, and those in the faces have embrasures, so as to fire out of one into the other, when taken by the enemy, and above there is a parapet twelve feet thick, with embrasures. These towers are expensive, and afford little resistance; and small bastions, without casemates, might be substituted in their room with advantage. The flanks of the counterguards are too small, and are easily destroyed from the opposite covert-way; and, therefore, they should either be enlarged or increased in number. The third method differs only from the former, in having two small flanks in each curtain, of about four toises, which can hardly hold two guns each, and, therefore, add no strength.

FORTIFICATION, according to count Pagan's method. This author establishes three sorts of fortification; viz. the great, mean, and little, whose chief dimensions are contained in the following table.

	Great Fortif.	Mean	Little
	Squares to all the other polyg.	Squares to all the other polyg.	Squares to all the other polyg.
Exter. sides	200	180	160
Perpendic.	17	30	21
Faces	60	60	45

For constructing the mean fortification, let AB (fig. 20.) be the side of a regular polygon, e. g. of a hexagon, and equal to a hundred and eighty toises. Bisect it in D , and erect a perpendicular equal to thirty toises, from the points

points A and B; draw through C the indefinite line of defence AN and BM; let the faces AE and BF be each equal to fifty-five toises; draw the flanks FN and EM perpendicular to the lines of defence, and MN will be the curtain. Count Pagan, in order to increase the fire of his flank, makes three flanks, raised one above another, and a second battery within the first. To construct these batteries, as they are commonly called, bisect the flank FN in G; through the points A and G draw the line AG, and produce it indefinitely within the battery; produce also the line of defence AN; take GH=5 toises, and through H draw the line HI parallel to FN or GN; draw LK parallel to HI, and at the distance of seven toises from it, and equal to fourteen toises from K to L; at the distance of seven toises from KL draw the parallel OP, making it equal to fourteen toises three feet from O to P; then draw through the point P the line PQ parallel to EB; this line will be the face of the interior battery, having P for its flank, and let a parapet, three toises thick, be constructed to the three flanks HI, LK, and OP. The great ditch is sixteen toises, and its counterescarp parallel to the faces of the batteries; the capital of the ravelin fifty, and its faces are drawn to the shoulders; the demi-gorges of the redoubts within the ravelin fifteen, and the faces parallel to those of the ravelin; the ditch of the ravelin twelve, and that of the redoubts five; the salient angle of the counterescarp is forty toises distant from that of the battery, and nine or ten broad at the extremities; the ditch before the counterescarp is twelve, the covert-way four, and the faces of the places of arms eight, and parallel to the opposite counterescarp. See fig. 21. N° 1.

This method, though at first received with great applause, has its defects; its three flanks are too near each other; the ditch before the redoubt is but ill defended, which should never be made without making tenailles likewise; the covert-way is too narrow, and the places of arms too inconsiderable for defending the place; and the want of traverses in the covert-way is a defect, especially since the modern discovery of ricochet batteries.

Fortification, according to M. Blondel's method, has a great similarity with that of the count de Pagan; only that the quantity of the lines and angles is differently determined. See fig. 22. and fig. 23. N° 2.

Mr. Blondel makes two sorts of fortification, viz. the great, whose exterior side he makes two hundred toises; and the little, in which it is one hundred and seventy toises. In order to find the angles made by the exterior sides, and the lines of defence, he directs to subtract 60° from the angle of the polygon, and to add 15° to the third part of the remainder, which will give the angle sought. E.g. the angle of an hexagon is 120°, from which take 60°, and the third part of the remainder 30° is 10, which added to 15, gives the angle required. The lines of defence are equal to $\frac{1}{2}$ of the exterior side, i.e. 119 or 120 in the little, and 140 in the great. The construction is as follows: let AB (fig. 22.) the exterior side of a hexagon, be one hundred and seventy toises; the angles ABC, BAD, twenty-five degrees each; the lines of defence AD, BC, one hundred and twenty toises; let O be the point of intersection of these lines; bisect AO, BO, in E and H; then will AE, BH be the faces; EC, HD the flanks; and CD the straight part of the curtain. The outposts EI, LH, are ten toises each; the flanks are retired five toises behind the lines EC, HD: in all polygons above an heptagon, M. Blondel makes the retired flanks from ten to twelve toises distant from these lines, in order to lengthen the curtains. Each flank exceeds the flank before it nine feet in height, and they are eight toises distant from outline to outline. The counterescarp of the ditch is drawn from the extremities I, L, of the outposts, parallel to the faces of the batteries; the counterescarp is but four toises broad, ten or twelve feet of which are taken for the parapets; the ditch before them is ten toises. If from the shoulder E, as a centre, an arc be described through H, and another from H through E, the intersection of these arcs will be in the salient angle of the ravelin, the faces of which are directed to a point in the faces of the batteries within six toises of the shoulders; the gorge of the ravelin is determined by producing the faces of the counterescarp; the ditch of the ravelin is twelve toises. The demi-gorges of the lunettes V are twenty toises; their faces parallel to the counterescarp of the ditches, before the ravelin and counterescarp, and the ditch before them is eight toises; the covert-way six, and the faces of the places of arms, which are likewise parallel to the counterescarp, are as much. The retired batteries, a, in the batteries and ravelins, are seven toises from the faces; and their lengths are determined by the faces and counterescarp of the ravelins and counterescarp produced. This method is very expensive, and requires a numerous

artillery for defence. His three flanks are too near each other, and too open, and, therefore, liable to be destroyed from the covert-way, for the counter-guards are not broad enough to screen those flanks; the low batteries a, &c. are too narrow and confined; and his places of arms are too small; his great ditch is too wide; and the omission of traverses in the covert-way is important, since the use of ricochet batteries.

Fortification, according to the fifth method of Baron de Cöcher, This first method is applied to a hexagon, and it is supposed that the surface of the water is but four feet lower than the level ground. Let AB, (Tab. III. fig. 24.) the interior side of an hexagon, be one hundred and fifty toises; take AC, BD, each equal to 30, and the capitals AE, BF, each 80, and AG, BH, 40; from E and F draw the lines of defence to D and C, and through G, H, lines parallel to ED, FC, in which take GI, HK, each equal to forty toises, for the higher faces of the batteries. For the lower faces EM, FN, draw IO (fig. 25. N° 2.) perpendicular to IG, and equal to four toises; or parallel to IG, and = 4 toises; then will FM, perpendicular to EM, determine the lower face EM. In order to determine the tower 3, in M take MS=5 toises; draw Sm parallel to EM and = 14 toises; in Or produced, take rs=4 toises, and in EM take MV=8 toises; then if the points s and r are joined by a right line, and m, V, by an arc of 60°, we shall have the outline of the tower. From the points C and D (fig. 24.) set off on the lines of defence fourteen toises to Y and W, and on the bases YI and WK describe equilateral triangles, and the angles opposite to these bases will be the centres of the higher flanks YI and WK; and R being the intersection of the two lines of defence, bisect RM in S, and RC in Q, and drawing SQ, & SR will be half the smaller; and drawing from C a line parallel to IY, to as to meet the tower, on this the mean flank may be defended in the same manner as the former. The parapets of the three flanks, and those of the parts mV, VM (fig. 25. N° 2.) of the towers, are twenty-four feet thick; the other parts Mr, rm, sixteen, and all the other parapets, in general, are twenty feet. Behind the lower parapet there is a banquet of three feet, and a rampart of five; and under this rampart a stone gallery running from one end to the other, and divided into several apartments, which are shut from without; and also another, going from the salient angle of the lower faces to that of the higher, with loop holes facing the dry ditch X, (fig. 24.) which lies between the higher and lower faces of the batteries; and likewise a row of palisades, parallel to the higher faces, and four toises distant from them. Before the mean flank there is a wet ditch six toises broad, and another 2 (fig. 25.) behind the towers of the same breadth, over which there are two draw-bridges, parallel to the higher faces. The ditch z is flanked by two counterforts in Or, and the dry ditch by two in IO. The great ditch is twenty-four toises broad, and its counterescarp parallel to the lower faces of the batteries; the demi-gorges OL of the ravelin (fig. 24.) are twenty-nine toises each; and the faces LP, forty-nine; the dry ditch Y is sixteen toises; the rampart twenty-eight feet and the lower faces T are parallel to the higher ones, the parapet of which is twenty, and the banquet three. In the gorge of the ravelin there is a small redoubt a, about five feet high, and underneath a lodgment of stones, the walls being eighteen inches thick at the sides; the roof is made of planks, covered with three feet of earth. There is a dry ditch going from the extremities of the faces to the redoubt, and round its angle, having a row of palisades before it to secure the retreat from the ravelin into this redoubt; there is likewise another row going from the extremities of the faces, in a round form, turning towards the gorge of the ravelin. In the dry ditch of the ravelin, within six toises from the great ditch, is a coffer, and a ditch p of six toises before it; this coffer has a wall on both sides, and the roof is planked and covered with a foot and a half of earth; above this is a stone parapet of five feet high, with a banquet behind it. There runs a covered gallery under the rampart of the lower faces, and another joining the two salient angles, together with a row of palisades, in the same manner as in the dry ditch before the batteries. The wet ditch before the ravelin is eighteen toises; the counterescarp, which the author calls *voir face*, is twenty-five feet broad, and the ditch before them is fourteen toises; the covert-way is twelve toises broad, and the glacis twenty; the demi-gorges f, g, h, of the places of arms, are twenty-two toises, and are taken from the point g, where the branches of the covert-way meet, and the faces f, h, b, are twenty-eight; within these places of arms are traverses of twenty feet thick, and eighteen toises long, within ten or twelve feet from, and parallel to the faces. The stone lodgments b, within the places

of arms, are found by setting off twelve toises from the point *g*, for the semi-gorges, and the faces are drawn parallel to those of the places of arms. At six toises from the places of arms, are coffers *g* of eight feet broad, made with planks at the sides, and above with a foot of earth over and before them. There are two banquettes all round the covert-way, and before the traverses, as also two rows of palisades before the traverses, one of which joins them, and the other goes round the covert-way. Lastly, the re-entering angles of the counterescarp, next to the covert-way, are made a little round, as likewise that in the ravelin; but the contrary way is, if they are made hollow.

FORTIFICATION, according to Coehorn's second method. In this method the level of the ground is supposed to be three feet above the surface of the water, and AB, fig. 26, is the interior side of a heptagon of a hundred and twenty-six toises; take in the capitals, AC, BD, each of twenty-two toises; at the extremities C, D, make the angles ACE, BDF, each of forty degrees; and set off sixty-six toises for the faces CE, DF, of the bastions; on the interior side, take AG, BH, each of thirty toises, and from the point D as centre, describe an arc through the point G, on which set off a chord of thirty; and on this chord describe the mean flank GI, which is an arc of sixty degrees.

Draw a line from the salient angle D through the extremity I of this flank, on which take Ia of ten toises; join aL, on which describe the orillon as usual.

The outline of the higher flank is twelve toises distant from that of the outline of the mean; this flank is an arc described from the same centre as that of the former, the chord of which is forty toises.

From the points G, H, draw the broken parts of the curtain perpendicular to the capital of the bastion, and make it nine toises long; the extremity of the higher flank is terminated, by the inside line of the parapet of the curtain produced.

The tenaille is found by producing the faces of the bastions ten toises; through the extremity of which an arc is described from the opposite salient angle of the bastion, as centre; on this arc is set off a chord of twenty toises; and this chord serves to describe the flank upon, which is an arc of sixty degrees; the curtain is a right line.

There is a wet ditch before the tenailles, of ten toises broad, with two bridges at each end, near the orillons; the one directly over it, and the other along the face of the bastion.

The dry ditch round the body of the place is twenty toises broad, before the faces of the bastion to which it is parallel, and the lower rampart KL twenty-nine feet; the semi-gorges ML are fifteen toises, and the flanks LN, eighteen, and are described from the salient angles K of the lower faces as centres.

The salient angle of the ravelin is a hundred and twenty-five toises distant from the curtain of the body of the place, and is twenty degrees; the faces are fifty toises long; the faces of the redoubt *x*, are sixteen toises distant from those of the ravelin, and fourteen long.

The wet ditch round the lower faces of the ravelin is twenty-four toises broad; the work beyond this ditch, which the author calls the second counterescarp, is twenty, parallel to the ditch.

To find the broken part of this work, join the two re-entering angles *m*, *r*, on which take *mr*, of thirty toises, and draw *rt*, *rv*, parallel to the outline of the counterescarp, each equal to twelve; set off twenty-two from *t* to *s*, and from *v* to *q*; and upon these lines as chords describe the round flanks, which are arcs of sixty degrees. The traverses in this counterescarp are drawn at ten toises from the flanks perpendicular to the parapet.

The redoubts *z* in the re-entering angles, are found by setting off sixteen toises from the points *m* to *n* for their capitals, and the faces are parallel to the broken curtain before them: these marked *y* which are in the salient angles are found by producing the counterescarp of the great ditch, and setting off twelve toises from the points of their intersections for their faces *z*, and the flanks are drawn parallel to their capitals.

The ditch before this work is fourteen toises; as to the covert-way and glacis, they are the same as in the author's first method.

FORTIFICATION, according to Coehorn's third method. Here the level of the ground is five feet above the surface of the water, and the author supposes an octagon, whose interior side AB, fig. 27, is a hundred and ten toises; the semi-gorges AC, BD, twenty-one; the capitals AC, BD, of the bastions sixty-four; and the salient angles eighty-five degrees; the faces CE, DF, of the bastions fifty-four toises; the parts Q₁, Q₂, of the tenaille thirty-two; the lower flanks, that is, those of the tenaille, are found by describing arcs through the points, *s*, *r*, from the

opposite salient angles DC, on which are twenty toises set off as chords; and these chords serve to describe arcs of sixty degrees upon, for the required flanks.

From the extremities *v*, *t*, of these flanks, lines are drawn to the opposite angles D, C, and six toises set off from *v* to *q*; and upon *qE* the orillon is described as usual. The higher flanks are described from the same centres, as the lower through the extremities *n*, *m*, of the curtain; and their chord is thirty toises.

The wet ditch before the body of the place is twenty toises, and its counterescarp parallel to the faces of the bastions.

The capital VW of the detached bastion is a hundred toises; the faces are directed to the salient angles of the inner bastion; the dry ditch behind the lower faces in the detached bastion is twenty toises; and the higher faces are parallel to the lower; and thirty-one toises long; the towers *x*, and the ditch before them are made in the same manner as in the first method. To find the flanks, make the semi-gorges VA, VB, each thirty-eight toises, and draw the chords of these flanks, parallel to the capital VW; and from the extremities of the higher faces draw also lines to the former, upon which the flanks are described as usual.

The counterescarp of the ditch before the redoubt *z*, is drawn from the extremities of the flanks parallel to the faces; and at six toises from this, the faces of the redoubt are drawn; four toises of which are cut off from the flanks.

The ditch before the detached bastion is twenty-four toises; the ravelin, counter-guards, covert-way, and glacis, are the same here as in the first method.

There are little pits or ponds *l*, *l*, dug between the higher and lower curtains, to hold water, in order to prevent the passing from the tenailles to the flanks.

Mr. Muller has urged a number of objections against Coehorn's first method, for which we must refer to his *Elements of Fortification*, p. 91, &c. and as to the second and third, they are absolutely impracticable. However, Coehorn's works were published before he had acquired that experience which afterwards rendered him one of the greatest engineers; and Bergen-op-zoom, which he fortified, is one of the best contrived fortifications in all Europe.

FORTIFICATION, according to the method of Schöner. This method is divided into the great, mean, and little: the exterior side of the polygon for the great fort is two hundred toises, for the mean fort one hundred and eighty, and the small one hundred and sixty. The line of defence in the first is one hundred and forty toises, in the second one hundred and thirty, and in the third one hundred and twenty. This line is always salient. All the other lines are fixed at the same length for all polygons, whose structure chiefly depends upon the knowledge of the exterior side, of the capital, and of the flanked angle: for which consult the following.

TABLE of Capitals and flanked angles.

Polygons	IV	V	VI	VII	VIII	IX	X	XI	XII
The flanked angle in the three sorts of fortification	64	76	84	90	95	97	99	101	103
Capital for the great fort	46	49	51	52	53	54	56	57	59
Ca. for the mean fort	42	44	46	48	50	51	52	54	56
Ca. for the small fort	39	41	42	44	46	47	48	50	52

Scheiter detaches the bastions from the curtain, and forms a kind of recess behind the curtain (suppose an octagon to be fortified with his greater fortification) let AB, (Tab. IV. fig. 28) be its exterior side, and equal to two hundred toises; A, C, BD, parts of the radii, equal to forty-six toises, be the capitals, and draw the interior side CD: In the compass take a hundred and forty toises for the line of defence, and putting one leg in the flanked angle A, describe with the other an arc to cut the interior side in E; make CF=ED, and draw through F and B the second line of defence FB; at E and F, on the lines of defence AE and FB, erect the perpendicular EL and FI, which, meeting the lines of defence alternately, determine the faces of the counter-guards, or detached bastions of Scheiter. Produce the lines of defence towards the capitals, and take the parts EH and FP, each of sixteen toises, and bisecting these lines, draw the higher flanks parallel to the lower, and make the same construction on the other side; take the distance PQ, and with one leg of the compass in P, describe an arc to intersect the capital in the point N; draw NQ and NP, and the counter-guard will be finished. About the counter-guard make a large ditch of eighteen toises, which will give the redan RST, and as the scarp of this ditch forms a salient

salient angle towards the middle of the curtain, Scheiter, in order to remedy this inconvenience, constructed there a small bastion in the following manner: from the point 3, where the lines of defence intersect one another, he let fall a perpendicular 34 on the interior side; and from the point 4 on each side, he took the distances 45 and 46, each equal to 47; and then drew the lines 53 and 36 of this bastion. The flanks are drawn parallel to the perpendicular 34, and produced till they meet a parallel to P F and E H. The ditch of the counter-guards is formed by producing the faces of twenty toises, as ZA to X, and drawing a line from X to the angle of the shoulder 1, &c.

On the re-entering angle of the ditch, Scheiter describes a kind of redoubt K, the capital of which is sixteen toises; the counter-guards are encompassed with *sauf-braines*, as well as the whole interior inclosure, except the faces of the small bastion in the middle of the curtains: he also adds a covert-way to that of the place, at the foot of the glacis of the first. This system of Scheiter differs essentially from that which M. Vauban executed in the fortification of New Brissac; and yet some have groundlessly charged Vauban with having borrowed his from this of Scheiter.

Fortification, according to M. Belidor's first method. Let A B, fig. 29, be the exterior side of an octagon, and equal to two hundred toises; the perpendicular C D, fifty; the faces A E, B F, seventy; and the flanks are found according to M. Vauban's method.

The line joining the extremities a and b of the flanks of the same bastion, serves as an exterior side for tracing the front of a polygon, whose perpendicular e d is thirteen toises, the faces twenty-two; the parts d f of the lines of defence, which terminate the flanks, are fourteen; the dry ditch before this front is ten toises at the points a, b, and the counter-scarp terminates at the opposite shoulders.

The rams-horns g, are described from a point, in the middle of the faces of the interior front as centres, with a radius of twenty-five toises.

The retrenchments H, are drawn from a point h in the face at fifteen toises from the shoulder to the points i, a, and are twenty-five toises long; the orillons k l, eight, and the flanks n are eight toises retired near the orillon; which are the chords of an arc from the opposite shoulder; the ditch before these retrenchments is eight toises near the parapet of the bastions, and its counter-scarp directed to the shoulders.

The salient angle of the redoubt B touches the intersections of the curtains, produced, and the faces terminate on the faces of the inner front within three toises of the shoulders; its ditch is three toises; these redoubts are a stone wall of three or four feet thick, with loop-holes in the faces.

M. Belidor has made no outworks to this system, but Mr. Muller has added ravelins and a covert-way, made in the usual manner; the great ditch is twenty toises before the salient angles of the bastion, and its counter-scarp is directed to the shoulders; and the faces of the ravelins to the out-line of the retrenchments H.

Fortification, according to M. Belidor's second method. A B, fig. 30, is the exterior side of an octagon of two hundred toises; the perpendicular C D, fifty-five, and the faces A E, B F, seventy, as in the former; and the flanks are likewise found according to M. Vauban's method.

The line a b, which passes through the extremities of the flanks, serves as an exterior side to the inward polygon, whose perpendicular e d is five toises, the faces twenty-four, and the flanks are chords of arcs described from the opposite shoulders of the detached bastions as centres.

This inward polygon is nothing else but a strong wall, behind the curtain of which, and about eighteen feet distance from it, is a parapet or epaulement of earth three toises thick; and within the bastions are cavaliers, whose fronts are circular arcs described with a radius of about twenty-three or twenty-four toises; the flanks are seven toises long, and gorges thirty-two.

The counter-scarp of the ditch before this polygon is seven toises at the salient angles a, b, and parallel to the curtain.

The rams-horns or tenailles touch the lines of defence within three toises of the shoulders, and are described so as to meet the other lines of defence in the same point as the counter-scarp of the inner ditch.

The outline of the curtain between the rams-horns is nine toises from the ditch.

The exterior side h k of the retrenchments within the detached bastions, meet the faces within twenty toises from the shoulders; the perpendicular m n, is seventeen, the faces h i, twenty; the chord on which the orillon is de-

scribed is five toises, as likewise the retired part of the flank; the flanks and orillons are made according to M. Vauban's method.

The circular curtain and the round part of the ditch behind it, are described with a centre, twenty-five toises distant from the points a, b.

The great ditch is twenty toises before the salient angles of the detached bastions, and is supposed to be dry; for which reason M. Belidor made a component to go from the curtain to the ravelin, eighteen or twenty feet wide, whose parapets terminate on both sides in a slope or glacis. The capital of the ravelin Q, is sixty-six toises, that of the redoubt P, thirty; the faces of the ravelin are directed to those of the retrenchments within the bastions, and those of the redoubt to the shoulders; the batteries in the ravelin are retired eight toises behind the faces; the ditch of the ravelin is twelve toises, and that of the redoubt seven.

The semi-gorges of the lunettes R, are twenty-five toises, and the faces perpendicular to those of the ravelin and the bastion; the ditch before them is eight toises, and the batteries S, are retired, as much, and are fifteen toises long; lastly, the covert-way is six toises.

Fortification, according to M. Belidor's third method.

The figure in this construction, is part of an octagon, whose side A B, fig. 31, is two hundred toises, the perpendicular C D, forty; the faces A E, B F, fifty-five; the parts D r of the lines of defence, between the perpendicular and the broken part of the curtain, thirty; and the length of the broken parts r n, twenty-five; the orillon is nine, and is a part of a flank found according to M. Vauban's method; the flanks are eight toises retired, and are arcs of sixty degrees; the outlines of the rams-horns are thirteen toises distant from each other; the passages at their extremities are three, the outmost or lowest is described with a radius of thirty toises, and the other is described from the same centre.

Mr. Muller has omitted the cavaliers placed in the gorges of the bastions, as being according to his notion, superfluous.

The centre R of the arc K L, is eighteen toises distant from the re-entering angle of the counter-scarp; the chord K L is forty-four toises, as well as the other face of the lunette; and the radius R N, eighty-eight; the battery H is ten toises retired.

The figure m is a redoubt made of a stone wall full of loop-holes, with a ditch of two toises before it.

The ditch before the lunettes is twelve toises at the salient angles, and its counter-scarp directed to the extremities of the opposite faces.

The capital of the ravelin W is forty-four toises, and semi-gorges, thirty one; the flanks are nine toises, and directed to the shoulders of the bastions.

The ditch before the ravelin is ten toises, and the covert-way six.

The glacis T, before the salient angles of the bastions, is fifteen toises broad; the semi-gorges of the places of arms X are twenty-six toises; and those of the redoubts or stone wall within them, twenty, reckoning from the edge of the glacis T; and the faces are drawn parallel to the opposite semi-gorges.

The redoubts S within the lunettes, are also made of a wall three or four feet thick full of loop-holes, with a ditch of three toises before them.

The dimensions of the arrows and detached redoubts, are the same as those in M. Vauban's method, only the arrows have flanks parallel to the passage of ten toises.

The several systems of Pagan, Vauban, Coehorn, Blondel, and Belidor, may be seen at one view in Tab. V. fig. 32.

Fortification, according to Mr. Muller's first method.

Let A B, Tab. VI. fig. 33, be the exterior side of a polygon any length, e. g. a hundred and eighty toises; make the perpendicular C D of any length, as the sixth, fifth or fourth part of the exterior side, according to the expense or importance of the place: here it is the first part or thirty toises; set off fifty toises or more for the faces B H, A L, or rather $\frac{1}{2}$ of the exterior side, from the salient angle A describe an arc with the radius A I of twenty toises, that is two or three toises more than the breadth of the ditch; draw from the opposite shoulder H a tangent H I to that arc, and from the angle A the indefinite line A b parallel to that tangent; then, if from the angle A as centre an arc a b be described with any radius, the flank G H is drawn parallel to the chord a b; one of the flanks being thus found, the others will be found by taking the distance D G, between the perpendicular and the angle of the flank, and carrying it from the extremities of all the perpendiculars on the lines of defence, as from D to F; this being done, the counter-scarp of the ditch is drawn parallel to the line H I or to a b; and having the points or re-entering angle O, its distance from the extremity of the perpendicular being carried all round will give the re-entering angles before the other fronts.

The tenailles *h k*, which M. Sédiar has invented, and called them *rams-horns*, are described, by setting off three toises from the shoulder *Q* of the bastion to the point *h*, and drawing *h f* perpendicular to the line of defence; then its intersection *f*, with the other line of defence produced, will be the centre of the arc *h k*.

In order to controul the ravelin, let off twelve or fifteen toises from the shoulder *E* to the point *r*, in the face of the bastion, and from the angle *G* of the flank as centre, describe an arc through the point *r*, meeting the perpendicular *C D* produced at *L*; from this point *L* draw the faces, *6*, as when produced to fall on the faces of the bastions within three toises of the shoulders; the ditch of the ravelin is twelve toises.

For the retired flanks, find the flank *Q R* as before, on which let off five or six toises for the shoulder or orillon; and from a point *g*, in the opposite face of the bastion at five toises from the salient angle *B*, draw the broken part of the flank; then draw the retired flank parallel to the line *Q R*, at five toises distant from it: the orillon may be made round in the manner of M. Vauban, if it be thought proper.

FORTIFICATION, according to Mr. Muller's second method, with detached bastions. Let the interior side *A B*, fig. 34, of an octagon be a hundred and thirty toises; take *A b*, *B n*, equal to twelve toises for the semi-gorges of the small bastions, and as much for their capitals *A c*, *B r*; from the points *c*, *r*, draw the lines *c n*, *r b*, to the extremity of the gorges, and make the flanks *b d*, *n m*, perpendicular to the lines of defence; the ditch is six toises at the salient angles *c*, *r*, and its counterescarp drawn to the extremities of the flanks of the detached bastions. The capitals *c*, *r*, *d*, of the detached bastions are fifty-five toises, and the lines of defence are drawn to the extremities *b* and *n* of the interior flanks; the faces are sixty; the radius of the arc, which serves to determine the position of the flanks, eighteen; and the ditch sixteen at the salient angle.

The ravelin is constructed by describing an arc from the extremity of the flank, as centre, through a point in the opposite face of the bastion, within twenty toises of the shoulder, which arc intersects the capital of the ravelin at the salient angle; the faces terminate within five toises of the shoulders, the semi-gorge of the redoubt *R* is fifteen, its faces parallel to those of the ravelin, and its parapet two toises; the ditch of the ravelin twelve, and that of the redoubt six.

The semi-gorges of the places of arms are twenty toises, those of the flane redoubts *p* within them twelve; the faces of the places of arms are twenty-five; and those of the redoubts parallel to them, with a dry ditch of three toises before them; the covert way is six, and the glacis twenty.

The faces of the tenailles are sixteen toises, the passage between them and the flanks of the bastions three; their flanks are parallel to the others, the curtain is drawn through the points where they meet the lines of defence, and the inside of the tenailles is terminated by lines drawn through the extremities of the flanks of the detached bastions.

FORTIFICATION, according to Mr. Muller's third method, with detached orillon bastions. Let the exterior side *A B*, fig. 35, of an octagon be two hundred toises, the perpendicular *C D* forty, that is, a fifth part of the exterior side, the faces *A E*, *B F*, fifty-five; the radius of the arc which serves to determine the position of the flanks, twenty-two; the ditch sixteen at the salient angles; the orillon five; the flank is retired five toises; and the line *k d*, which terminates the flanks, is drawn from a point *d*, in the face at five toises from the salient angle; the shoulders of the tenailles are twenty toises from those of the bastions; the flanks parallel to the others, and the curtain is drawn through the points of intersection of the flanks and lines of defence.

Take on the lines *E F*, *F H*, drawn from the extremities of the faces parallel to the flanks, and which terminate the inside of the tenailles, the parts *l n*, *h m*, each of six toises, for the breadth of the ditch; and upon the exterior side *z n*, construct a front of a polygon, by making the perpendicular twelve, and faces twenty toises. The redoubts *V* are made of a wall three feet thick only with loop-holes; their salient angle is determined by the counterescarp of the inner ditch produced; and the faces terminate within three toises of the shoulders; the ditch about these redoubts is four toises.

The ravelins and covert-way are constructed in the same manner as those in the former method.

Mr. Muller has made remarks on these several constructions, designed to shew in what respects they are superior to those of M. Vauban, already recited. See Muller's *Elem. of Fortification*, p. 100, 104, 108, &c.

FORTIFICATION, profile of a, is a representation of a ver-

tical section of a work, serving to shew those dimensions which cannot be represented in plans, and are necessary in the building of a fortification. This profile is constructed in the following manner: provide a scale of equal parts, adapted to the perpendicular height of the work.

c. gr. let *a b*, *Tab. VII. fig. 37*, be a scale of twenty toises, and let *A B* represent the level of the ground plane, so that those parts of the fortification which are above the surface of the ground, or below it, may be above or below this line in the profile. From the point *A*, in the line *A B*, take *A C* = 2 toises three feet, for the interior talus or slope of the rampart; at *C* erect a perpendicular *C D* of three toises eighteen feet for the height of the rampart; through the point *D* draw an indefinite line *D N* parallel to *A B*, in which take *D F* = 5 toises for the breadth of the terre-plain of the rampart; at the point *E* erect the perpendicular *E F* = 2 feet from the height of the banquette, and draw *F H* parallel to *D N*, making *F G* and *G H*, each equal to four feet. Draw the line *E G*, which will represent the talus of the banquette, and *G H* will be the upper part of it; on the point *H* erect the perpendicular *H I* = 4 feet from the height of the parapet above the banquette. From *I* draw the indefinite line *I K* parallel to *D N*, in which take *I L* = 1 foot and draw *H L*, which will be the interior side of the parapet; take *L K* = 3 toises for the thickness of the parapet; and from the point *K* let fall the indefinite line *K P*, perpendicular to the line *A B*, and produce it below *A B*; in this line take *K M* = 2 feet, and draw the line *L M* for the upper part of the parapet, which is a talus, that the soldier on the banquette may be able to discover the covert way and the glacis. On the point *N*, where *D N* intersects *K P*, as a centre, with a radius of one foot, describe a small semi-circle, which represents the *casemate*; take *N P* = 6 toises, and from the point *P* draw an indefinite line *P n* parallel to *A B*, which will represent the bottom of the ditch, the depth of which is supposed to be equal to the height of the rampart.

Take *N O* = 5 feet for the thickness of the revêtement of the curtain, and from the point *O* draw the indefinite line *O Q* parallel to *N P*; this will be the interior side of the revêtement of the point *P*, where the line *P n* meets the line *N P*; take *P R* = 7 feet, or about the fifth part of its height *N P*, for the talus of the revêtement, and draw the line *N R*, which represents the scarp or exterior side of the revêtement; take *R S* = 1 foot for the jutting of the foundation, and draw *S T* perpendicular to *P n*, making it equal to two or three toises from the depth of the foundation; draw *T Q* parallel to *P n*, and let it intersect *O Q* in *Q*; and let *Y* & *be drawn parallel to N M, and at the distance of three feet, for the revêtement of the parapet. In order to represent the profile of the counterfort or buttress, when there is any, take O V = 9 feet, and draw V X parallel to O Q; V X, Q O, will represent this profile, by means of which the revêtement O R is strengthened. That the terre-plain of the rampart may have a proper declivity, for carrying away the water which falls upon it, let D W be equal to 1 foot, and draw W E, which will represent the upper part of the rampart, and the line A W represent the slope of its interior side. Suppose the breadth of the ditch to be twenty toises, and lay this down from P to n; and on the point n erect the perpendicular n m, terminated by the line A B at m, which will be the limit of the counterescarp. At the distance of three feet from this line, and parallel to it, draw a y, which will give the thickness of the revêtement of the counterescarp; n m = 3 feet will be the talus of this revêtement, and the line n m the exterior side of it. The foundation may be made to terminate at the distance of about six inches from the point u. Let m e = 5 toises be the breadth of the covert-way, and at the point e erect a perpendicular e d = 2 feet for the height of the banquette. Draw d f parallel to A B, and equal to one toise, in which take d e and e f, each equal to three feet.*

Draw the line e f for the talus of the banquette, and e f will be the upper part of it: from the point f erect a perpendicular f l = 4 feet, for the height of the parapet of the covert-way above the banquette. Produce l till it cuts A B in r; take r g = 20 toises from the breadth of the glacis, and draw l g, which will represent the glacis, or the declivity of the rampart of the covert-way: in this line take l h = 1 foot, and draw h f, which will be the interior side of the parapet of the covert-way; after which let there be a palisade constructed on the banquette, and the profile is finished. Encyclopedia.

FORTIFIED place, a fortress, or fortification, i. e. a place well flanked, and sheltered with works. See *Tab. Fortification*, fig. 21, with the explanation annexed to it, and fig. 38, which represents a fortified place beleagued.

Places fortified after the modern way, consist chiefly of bastions and curtains, and sometimes of demi-bastions, according

to the modern way, consist chiefly of bastions and curtains, and sometimes of demi-bastions, according

to the modern way, consist chiefly of bastions and curtains, and sometimes of demi-bastions, according

coding to the situation of the ground; of cavaliers, ramparts, faulx-brayes, ditches, counterescarpes, covert-ways, half-moons, ravelins, horn-works, crown-works, out-works, cplaudes, redoubts, and tenailles. See each under its proper article, **BASTION**, &c.

There are other moveable and additional parts; as *bermes*, *parapets*, *banquettes*, *embrasures*, *cordons*, *boyaux*, *mon-liets*, *chevaux de frise*, *chasse-trapes*, *galleries*, *manne-tiers*, *batteries*, *faps*, *mines*, *windis*, *gabions*, and *palisades*. See each in its place, **BERME**, **PALAPET**, &c.

Several of these works, again, consist of diverse parts, which have different denominations: thus, a bastion consists of *faces*, *flanks*, *casemates*, *orillons*, *gorge*, &c. which see.

FORTIN, or **FORTLET**, a diminutive of the word *fort*, importing a little *fort*, or *conce*, called also *field fort*.

Star Fort, is that whose sides flank each other, &c. See *Star Fort*.

FORTIORI. A multis **FORTIORI**. See **MULTO**.

FORTIS AQUA. See **AQUA FORTIS**.

FORTISSIMO, in the Italian *Musica*, is used to signify very strong. It is sometimes denoted by *FFF* or *fff*, and intimates that the performers are to play or sing very loud or strong, to express some passion, &c. See **FORTE**.

FORTRESS. See **PORT** and **FORTIFICATION**.

FORTUNA AQUILA. See **EQUESTRIAS**.

FORTUNA, in our ancient *Low-Low*, is the same with what we call **TREASURE-TREVE**.

The fortune ducis fortuna invenit inquirendum est per 12 juratos pro rege, &c. quod fideliter praestabunt, &c. omnes fortunas, abjurantes, appella, &c.

Some pretend it also signifies *fortune omnia*; but this seems to be very fanciful.

FORTUNATE (*lands*), in the *Ancient Geography*, an appellation which has given the critics and antiquaries great perplexity; being the name of a place famous for golden apples which grew there; or, as *Vario* says, for sheep with golden fleeces.

The ancients describe them as situate without the streights of Gibraltar, in the Atlantic ocean. The common opinion of the moderns takes them for the Canary islands; this is grounded principally on the situation and temperature of those islands, which render the use of cloths there unnecessary; and from the abundance of oranges, lemons, grapes, and other delicious fruits growing there.

Ol. Rudbeck has found a very different place for them. That learned author, who makes his native country, Sweden, the scene of all that is great and extraordinary in ancient tradition and fable, will have the *Fortunate Islands* to be Sweden; and the delicious fruits, talked of by the ancients, his imagination suggests, were nothing but the virtue and good manners, which anciently flourished in that cold hyperborean nation.

FORTUNE. See **PROVIDENCE**, **FATE**, &c.

FORTUNE, *Teve*, is a name unknown in the earlier ages; and does not occur either in *Homer* or *Hesiod*; as not being invented in their time.

In after-days it was introduced as a machine; and made to serve divers purposes in natural philosophy and theology.

Ptolemy, in an express treatise of the *Fortune* of the Romans, accounts for the practice of the ancient poets, who seem to make Jupiter the author of all the evils of life. Mankind, he observes, before the name of *Fortune* had got into the world, perceiving a certain arbitrary cause, disposing of things in an irrepressible manner, called it *God*; but the same cause being often observed to act at random, and without any rule or order at all, the supreme Being came to be divested of the attribute; and *Fortune*, or *Destiny*, acknowledged in his stead.

It is not easy to unravel what the ancients meant by the name *Fortune*. The Romans understood by it a principle of fortuity, whereby things came to pass, without being necessitated thereto; but what and whence that principle is, they do not seem to have ever precisely thought; whence their philosophers are often intimating, that men only framed the phantasm *Fortuna*, to hide their ignorance; and that they call *Fortune* whatever befalls a man without his knowing for what purpose. Hence *Juvenal*, sat. x. ver. 366, affirms, they were men who made a deity of *Fortuna*.

*Natum nomen abest, si sit prudentia, sed te
Nisi facimus, Fortuna, deum, curaque loquimur.*

The ingenious Mr. Spence gives another reading of this passage:

*Nullum nomen habet, si sit prudentia, sed te
Nisi facimus, Fortuna, deum, curaque loquimur.*

This reading, he thinks, agrees best with the context: *Juvenal* says, ver. 366, that the two things we should pray for are good health and good sense; that we might

be the authors of our own happiness if we pleased, ver. 363, that virtue is the only way to true happiness, ver. 364, that if we ourselves are prudent, *Fortuna* has no power over us; and that, in truth, there is no goddess at all, and has only usurped a seat in heaven from the folly of mankind, ver. 366. *Fortuna* was not considered as a deity by the old Romans, but was made so by the devotion and folly of the vulgar; and Mr. Science says, that he has seen an ancient gem, in which *Cybele*, the mother of the gods, is represented as turning away her head from *Fortuna*, in an attitude of disowning and rejecting her. *Polymetis*, p. 150, 151, &c.

According to the opinion of the heathens, therefore, *Fortuna*, in reality, was only the arrival of things in a sudden and unexpected manner, without any apparent cause, or reason; so that the philosophical sense of the word coincides with what is vulgarly called *chance*.

But in religion it had a farther force; altars and temples in great numbers were consecrated to this *Fortuna*, as a deity. This intimates that the heathens had personified, and even deified, their chance; and conceived her as a sort of goddess, who disposed of the fate of men at her pleasure. Hence that invocation of *Fortuna*, *O diva, proutum qua regis Italiam*; in the thirty-fifth ode of the first book, where he recommends *Augustus*, then preparing for a visit to Britain, to her protection. From these different sentiments it may be inferred, that the ancients at one time took *Fortuna* for a preceptory cause, bent upon doing good to some, and perfecting others; and sometimes for a blind, inconstant cause, without any view or determination at all.

If then the word *Fortuna* has no certain idea in the mouth of those who erected altars to her; much less can it be ascertained what it denotes in the mind of those who now use the word in their writings.

They who would substitute the name *Providence* in lieu of that of *Fortuna*, cannot give any tolerable sense to half the phrases wherein the word occurs.

Horace paints the goddess, preceded by *Necessity*, holding nails and wedges in her hands, with a cramp-iron, and melted lead to fillen it; rarely accompanied with *Fidelity*, unless when she abandons a family; for in that case *Fidelity* never fails to depart with her, as well as *friend*.

She is disreputably spoken of by most of the Roman writers, and represented as blind, inconstant, unjust, and delighting in mischief. *Orat. ad Liv.* ver. 52, ver. 374. *Hor. lib. i. od. 32.* ver. 26. *lib. iii. od. 29.* ver. 51. *Statius*, *Theb. xii.* ver. 605. However, they had a good as well as a bad *Fortuna*, a constant and inconstant *Fortuna*, the latter of which was represented with wings, and a wheel by her. *Hor. lib. iii. od. 29.* ver. 56.

Juvenal alludes to a statue of *Fortuna*, which exhibited her under a very good character, as the patroness of the poor infants that were exposed by their parents in the streets. *Sat. vi.* ver. 605.

The painters represent her in a woman's habit, with a bandage before her eyes, to shew that she acts without discernment; and standing on a wheel, to express her instability. The Romans, says *Lactantius*, represented her with a cornucopia, and the helm of a ship, to shew that she distributes riches, and directs the affairs of the world. In effect, it is with such characters, that we see her represented on so many medals, with the inscriptions, *FORTUNA AVG. FORTUNA AEDXX. FORTUNAE AVG. OR REDUCTE*, &c. Sometimes she is seen pointing at a globe before her feet, with a sceptre in one hand, and holding the cornucopia in the other.

The Romans had a virtue, as well as a malevolent *Fortuna*, for the objects of their adoration: the *Fortuna virtutis* was honoured by the men, and the *Fortuna mulieris* by the women.

They honoured *Fortuna* also under a variety of other appellations. The Romans derived the worship of *Fortuna* from the Greeks, under the reign of *Servius Tullius*, who dedicated the first temple to her in the public market. Nero also built a temple to *Fortuna*. The *Fortuna* worshipped at Antium was probably of the most exalted character of any among the Romans; if we may judge by the account which *Horace* gives us of the great solemn processions that were made to her. *Hor. lib. i. od. xxxv.* ver. 22. But the most celebrated temple of *Fortuna* was at *Præneste*. *Statius* speaks of several *Fortunas* there, and calls them the *Prænestina jaces*. *Lib. i. Sylv. iii.* ver. 80.

On the reverse of a medal of *Commodus*, we have a representation of *Fortuna*, under the quality, or surname of *Manent*, i. e. *stable*, permanent; holding a horse by the reins. On the Greek medals we meet with *ΑΙΤΑΘΗ* or *ΚΑΙΡΟΤΥΧΗ*, *God Fortune*. Constantine gave the epithet *ambrosia*, i. e. *ambrosial*, to the *Fortuna* of his new city *Constantinople*.

FORTUNE, part of. See **PART**.

FORTUNE-tellers. Pretenders to tell fortunes, and to any crafty science for the discovery of stolen goods, are punishable by imprisonment, pillory, and binding to their good behaviour, and shall be deemed vagabonds. Stat. 5 Geo. II. cap. 5. sect. 4. Stat. 17 Geo. II. cap. 5. sect. 2. See CONJURATION.

FORTY days. See QUADRAGESIMA, and LENT.

FORTY days' cure. See ATTACHMENT of the sheriff.

FORTY hours, prayers of. See HOURS.

FORTY shilling land is used in Scotland for a certain portion of arable land. The forty-shilling land of old extent contains eight oxgangs, or 104 acres.

FORUM, in *Antiquity*, is used in divers acceptations: sometimes for a place of traffic, answering to our market-places; in which sense it has usually some adjective added to it, as *forum horum*, the *high-market*; *forum piscarium*, the *fish-market*; *forum frumenti*, the *bread-market*.

FORUM, again, is used for any place, where the governor of a province convenes his people, to give judgment, according to course of law.

Whence a man is said *forum agere*, when he keeps the offices; *forum invidere*, when he appoints the place where they are to be kept, &c.

FORUM was also a public standing place in the city of Rome, where causes were judicially tried, and orations delivered to the people.

Of these *forum* there were several; at first only three, viz. *Romanum*, *Julianum*, and *Augustinum*; but that number was afterwards increased to six, by the addition of the *Transitorium*, called also *Palladium*; the *Treptanum*, and *Salustianum*.

The first, and most eminent of these, was the *forum Romanum*, called also *forum vetus*; and absolutely, *forum*, or *the forum*.

In this was an apartment, called the *BOSTRA*, where the lawyers pleaded; the officers harangued; funeral orations were delivered, &c.

In the same *forum* was the *curia*, or hall of justice, with the sanctuary of Saturn, the temple of Castor, &c.

FORUM is also used among casuists, &c. for justification. Thus they say in *foro legit*, or *the same forum*, i. e. in the eye of the laws, or the common course of justice: in *foro conscientie*, or *the inner forum*, i. e. in the eye of God, or a man's own conscience.

There are a great many things not condemned in *foro legit*, which yet are criminal in *foro conscientie*.

FOSS, or **FOSSÉ,** in *Fortification*, &c. a ditch, or MOAT.

The word is French, formed of the Latin participle *fossus*, of the verb *fodis*, I dig.

FOSS, advance. See ADVANCE.

FOSSÉ, can. See CAN.

FOSS, *Fossa*, in *Anatomy*, a kind of cavity in a bone, with a large aperture, but no exit, or perforation.

When the aperture is very narrow, it is called a *fovea*. In the cranium there are six internal, and fourteen external *fossæ*. The cavity of the orbit, which contains the eye, is a *fossa*.

FOSS is particularly used for the cavity, or denture in the back part of the neck.

FOSSA magna, or *navicularis*, is an oblong cavity, forming the inside of the *pudendum mulieris*, and which presents itself upon opening the labia; and in the middle whereof are the *caruncula myrtiformis*. See *Tab. Anat. (Splanchn.) fig. 9. lit. 1.*

FOSSA, in our *Ancient History*, was a ditch full of water, where women committing felony were drowned; as men were hanged. Nam *et ipse in semibus tenementis suis cum non ab antiquo legem habuisset iustitiam, videlicet fossam, fossam, fossam, et fossam*. In another sense it is taken for a grave, as appears by these old verses.

*Hic jacet in fossa Rode venerabilis viri
Hic est fossatus, qui bis erat hic cathedrat.*

Foss-way was anciently one of the four great Roman high-ways of England: so called, according to Camden, because it was ditched on both sides, which was the Roman method of making high ways.

FOSSARII, in *Antiquity*, a kind of officers in the Eastern church, whose business was to inter the dead.

Claudian relates, that Constantine created nine hundred and fifty *fossarii*, whom he took out of the divers colleges or companies of tradesmen: he adds, that they were exempted from taxes, services, burdensome offices, &c.

F. Goar, in his notes on the Greek Eusebiology, informs us, that the *fossarii* were established in the times of the apostles; and that the young men, who carried off the body of Ananias, and those persons full of the fear of God, who interred St. Stephen, were of the number. St. Jerome assures us, that the rank of *fossarii* held the first place among the clerks; but he is to be understood of those clerks only, who had the direction and intercession of the interment of the devout.

FOSSIL, in *Natural History*, is used, in a general sense, for any thing dug up, or found under ground. Such are all minerals, metals, rock salts, &c.

Fossil is used in a more confined sense by Linnaeus, to denote the third class of stones; and includes petrified, concrete, and terrene substances.

The chemists divide all bodies into three classes, or kingdoms; viz. *fossil*, or mineral, vegetable, and animal.

Fossils may be distinguished into, 1. Such as are natives of the earth; and, 2. Such as are adventitious, and deposited therein by any extraordinary means; as earthquakes, deluges, &c.

Fossils, natives, or **Fossils** properly so called, are sensible bodies, generated and growing in the earth, and found either buried in it, or lying on its surfaces; whose constituent parts are so simple and homogeneous, that there is no apparent distinction of vessels and juices; nor any difference between the parts, and the whole.

The first person who attempted to reduce the subject of *fossils* into a regular science, was Dr. Woodward, who published a method of arrangement, founded on the growth, structure, and texture of *fossils*. But this system being found insufficient for distinguishing the bodies of the *fossil* kingdom with accuracy, was succeeded by the method of dividing these bodies, according to the various changes produced on them by fire, into *calcaris*, *opris*, *vitrescentes*, &c. established by the Swedish and German authors; and this method now universally prevails. The microscopy of Wallerius is on this plan; however, other writers, as Dr. Hill, Menes de Costa, &c. have endeavoured to form a new system from the combined principles of Woodward and Wallerius; and arranged *fossils*, not only according to their growth, texture and structure, but also their principles and qualities, as discovered by the aid of fire and acid menstrua. Native *fossils* are either simple, or compound.

Fossils, simple, are those, whose parts, however divided, are all of the same nature, i. e. of the same gravity, magnitude, figure, hardness, and mobility.

Such is quicksilver, which, however divided, is always found the same.

Of *fossils* naturally and essentially simple, some, according to Dr. Hill, in his History of *Fossils*, are neither inflammable nor soluble in water, of which he reckons three series; as those of no regular structure or determinate figure, comprehending the simple *SAXUM*, of which there are several orders and genera; those of a regular structure, and no determinate figure, of which there are three classes, viz. the *TRACHES*, the *STRATIFORMES*, and the *CYSTIFORMES*, each of which is again subdivided into orders and genera; and those of a regular structure and a determinate figure, comprehending three classes, viz. the *TELESTITES*, *CRYSTALLI*, and *SPERMES*, which include various orders and genera. Other simple *fossils*, though unburnable, are soluble in water; such are the simple *SALTES*; and others, on the contrary, are inflammable, but not soluble in water; of which there are two series, viz. those of a solid form, comprehending the *PILODIDACTYLIA* and the *PHILOCTECTYLIA*.

Fossils, compound, are those which may be divided into different, or dissimilar parts.

As antimony, which may be resolved by fire into sulphur, and a metallic part.

Of these compound *fossils*, in the distribution of Dr. Hill, some are neither inflammable, nor soluble in water, of which there are four series; as those that are found in continued strata, comprehending the two classes of compound *GASTRES*, subdivided into *LOAMS* and *MOUTES*, and their subordinate genera; and *STONES*, including three orders, and under those eight genera; those again, that are formed in detached masses of a regular structure and determinate figure, comprehending the two classes of *SEPTARIAE* and *STRATOCYTITAE*; those formed in detached masses, of no determinate figure or regular structure, and composed of a crystalline or stony matter, deluged by an admixture of earth in various proportions, comprehending four classes, viz. the *ACROPHI*, the *SEMIPELLUCIDAE*, the *FRAGILES* and *XANDEI*; and those that are formed of a fine pellucid substance, of great hardness, and never souled by an admixture of earth, or any other coarse matter, but susceptible of elegant tinges from metalline particles, of which there are in only one class, including the pellucid *GASTRES*, of which there are two genera, viz. such as retain one simple and permanent appearance in all lights, as the diamond, the carbuncle, the ruby, the garnet, the hyacinth, the amethyst, the sapphire, the beryl, the emerald, the prasiolite, the chrysolite, and the topaz; and such as exhibit variable colours, when viewed in different lights, as the opal and asteria. Other compound *fossils* are soluble in water, but not inflammable, as all the metallic *SALTES*, some of which are found naturally in a solid form, as *VITRIOL* and *CHALCANTHUM*; and others in a liquid state,

stone, such as the water from which the blue Cyprian vitriol is procured; and others are inflammable but not soluble in water, of which there are three classes, viz. the MARCASITES, the PYRITES, and PHLOGONIA. Dr. Hill adds a third general division of fossils, including the metallic fossils, some of which are fusible by fire, and not malleable in their purest state: such are antimony, bismuth, cobalt, zinc, and quicksilver; and others are fusible by fire, but concrete again in the cold, and become malleable, or ductible, and ductile under the hammer: such are tin, iron, copper, silver, lead, and gold. See STONES.

FOSSILS, adventitious, or foreign, include the subterranean exuviae of sea and land animals, and even vegetables; as shells, bones, teeth, leaves, stalks, &c. which are found buried in great abundance, in divers parts of the earth. See Fossil PLANTS, SHELLS, WOOD, &c.

These extraneous fossils have employed the curiosity of several of our latest naturalists, who have each their several system to account for the surprising appearances of petrified sea-fishes, in places far remote from the sea, and on the tops of mountains; shells in the middle of quarries of stone; and of elephants teeth, and bones of divers animals, peculiar to the southern climates, and plants only growing in the East, found fossil in our northern and western parts.

Some will have these shells, &c. to be real stones, and stone plants, formed after the usual manner of other figured stones; of which opinion is our learned Dr. Lister.

That author, though he allows of petrified shells on the sea-shores, will by no means agree, that there are any such petrifications in the inland countries. The shell-like stones, found in our quarries, he contends, are *lapides sui generis*, and never were any part of an animal.

His reasons are, that their matter and texture are perfectly the same with that of the rock, or quarry, whence they are taken; as iron-stone shells are all iron-stone; spar, or crystalline, all spar, &c. Add, that the quarries of different rocks yield different sorts of these shells; and that there are no animals in nature, which yield any thing exactly like many of them.

But to this erroneous doctrine it is to be answered, 1. That these shells found under-ground, are often perfectly conformable to those in the sea in figure, substance, magnitude, &c. 2. The substance of these fossils often also differs essentially from the common substance of stones. It is true, we frequently find them covered, or impregnated with a mineral, or stony matter, which has gradually infiltrated itself into the pores; but it is in many cases easy to distinguish that matter from the substance of the shell.

Another opinion is, that these fossil shells, with all other foreign bodies found within the earth, as bones, trees, plants, &c. were buried therein at the time of the universal deluge; and that having been penetrated either by the bituminous matter, abounding chiefly in watery places, or by the salts of the earth, they have been preserved entire, and sometimes petrified.

Others think, that those shells, found at the tops of the highest mountains, could never have been carried thither by the waters, even of the deluge; inasmuch as most of these aquatic animals, on account of the weight of their shells, always remain at the bottom of the water, and never move but close along the ground.

They imagine, that a year's continuance of the waters of the deluge, intermixed with the salt waters of the sea, upon the surface of the earth, might well give occasion to the production of shells of diverse kinds in different climates; and that the universal saltness of the water was the real cause of their resemblance to the sea-shells; as the lakes formed daily by the retention of rain, or spring-water, produce different kinds.

Others think, that the waters of the sea, and the rivers, with those which fell from heaven, turned the whole surface of the earth upside down; after the same manner as the waters of the Loire, and other rivers, which roll in a sandy bottom, overturn all their sands, and even the earth itself, in their swellings and inundations; and that in this general subversion, the shells came to be interred here, fishes there, trees there, &c. See Journ. des Savans, 1715. p. 19. and Mem. de Trev. 1713. No body has set this system in a better light than Dr. Woodward, in his Natural History of the Earth. That author, pursuing and improving the hypothesis of Dr. Burnet, maintains the whole mass of earth, with every thing belonging thereto, to have been so broken and dissolved, at the time of the deluge, that a new earth was then formed in the bosom of the water, consisting of different strata, or beds of terrestrial matter, ranged over each other usually, according to the order of their specific gravities. By this means, plants, animals, and especi-

Vol. II. N° 139.

ally fishes, and shells, not yet dissolved among the rest, remained mixed and blended among the mineral and fossil matters; which preserved them, or at least assumed and retained their figures and impressions, either indentedly, or in relief.

Camerarius attacks this opinion of Dr. Woodward, and goes yet higher, and advances many new notions. He supposes, 1. That the greatest part of the shells now dug from under-ground, had been placed there before the deluge, that is, at the time of the creation, when God separated the earth from the waters. 2. That, without having recourse to the dissolution of the earth by the waters, one might suppose most of them to have slipped in at the chinks and crevices naturally happening after the waters were retired, and the earth sufficiently drained.

3. That particular inundations might have swept most of these shells into the places where we now find them. 4. That the sea may have wrought, or call up, most of these shells through subterraneous spiracles and canals. 5. That God has created divers stony and metalline bodies, perfectly like the vegetables and animals, which we see on earth, and in the sea.

To all these suppositions, Dr. Woodward answers, 1. That it is no ways probable, God should create such a number of shell-fish of the same species at once; and that purely with a design to destroy them all again so soon after; that among the fossil shells of the same species it is easy to distinguish those of different ages; that some appear precisely such as we now find them in the spring, the season when the deluge began; that they are not only shells we find under-ground, but also bones of quadrupeds, plants, and trees of extraordinary sizes, which are not of the number of aquatics; and lastly, that the waters were separated from the earth on the third day, and that none of these things were created, till afterwards. 2. That, on the second supposition, these shells would be disposed perpendicularly, and not horizontally, as they are always found; that we should sometimes find them in the clefts of the earth, where in fact there are none but what are broken. 3. That we have no acquaintance with any of these pretended inundations; that they could never have brought shells, flags, bones, and elephants teeth, from America, and the East Indies, to England, and the other parts of Europe; nor the fruits, pieces, and beeches, frequently found far greater than any of our growth. Add, that these particular inundations must have risen to the tops of the highest mountains, and of consequence they must have been general.

4. On the fourth supposition it must be held, that God did not only create all these several bodies in the entrails of the earth, but their several parts, and the separate pieces and fragments of those parts; a piece of shell, for instance; one side of a shell, which consists of two; a shell void of the fish it should contain; beads of corn, without the grain; pieces of cedar-bark, without the wood; pieces of bullocks hides without flesh and bones; human limbs without bodies; a bone without the rest of the skeleton; a tooth without the jaw, &c. Add, that the fossil shells have not only external, but essential resemblance to sea-shells; both, e. gr. yielding, by analysis, a quantity of sea-salt; that among the fossil teeth of fishes, we meet with some apparently worn; and, lastly, that the shell-fish, called *perla*, has a long sharp tongue, by means whereof it pierces other shells, and picks the fish out of them; and that in digging under-ground we actually meet with divers of these shells thus pierced. Can such minute thorough-paced resemblances be the accidental effects of a *vis a natura*? See MARINE REMAINS, PETRIFICATION, Fossil STONES, SHELLS, &c.

Fossil-plant. See PLANT.

Fossils, marine. See MARINE.

Fossil-ivory. See IVORY.

Fossil-salt. See SALT.

Fossil-wood. See WOOD.

FOSSORES, in Natural History, a name given to a species of small worms hatched from the eggs of a fly, which feeds on the parenchymatous substance of the leaves of plants, burying themselves between the two membranes. These animals in general are called by Reaumur *officariæ*, but as they greatly differ in their size, and in their manner of eating and destroying leaves, the small ones which eat but slowly, and gnaw their way in crooked furrows, are called by him *fossiles poræ*; and on the contrary, those which eat away all that lies before them, and are of a somewhat larger size, are called *fossiles magni*. See ARCADES.

FOSTER land, in our Old Writers, is land given or allotted for the finding of food or victuals; as for monks in monasteries, &c.

FOSTERLEAN, anciently signified nuptial gifts; much the same with what we now call JOINTURE.

The word is originally Saxon, and signifies *cibum exhibito*, that is, a stipend which the wife has for her maintenance. *Posita jaendum est cui fofterium pertinet, vadit hoc Brigandis, & pignus unius sui.*

FOTHER, or FODDER, is a weight of lead, containing eight pigs, and every pig one and twenty stone and a half; so that it is about a ton or common cart-load. Among the plumbers in London, it is nineteen hundred and a half; and at the mines it is two and twenty hundred and a half.

The word is of Teutonic origin, from *fuder*.

FOTHERING, in *Sea-Language*, is a peculiar method of endeavouring to stop a leak in the bottom of a ship while she is a float, either under sail, or at anchor. It is usually performed in the following manner: a basket is filled with shives, cinders, and chopped rope-yarns, and loosely covered with a piece of canvas: to this is fastened a long pole, by which it is plunged repeatedly in the water, as close as possible to the place where the leak is conjectured to lie. The oakum or chopped rope-yarns, being thus gradually flaken through the twigs, or over the top of the basket, are frequently sucked into the hole along with the water, so that the leak is choked, and the entrance of the water prevented. Falconer's Mar. Dict.

FOTOQUE, in the *Japanese*, *Theshey*, the name of an order of deities; the other order being called *CAMIS*. From the latter they obtain the blessings of this life, and from the former those which relate to a future life.

FOTUS, in *Medicine*, the same as **FOMENTATION**.

FOUCADE. See **FOUGATE**.

FOVEA ardis, the pit of the heart, or rather of the stomach, called also *foveolus cordis*.

FOUGATE, FOUGASSE, or FOGADES, in the *Art of War*, a little mine, in manner of a well, seldom exceeding ten feet in width, and twelve in depth; dug under some work, or post, that is like to be lost; and charged with barrels, or sacks of gunpowder, covered with earth. It is frequently placed before the weakest parts of a fortification, as the salient angles and faces, not defended by a cross-fire, and is set on fire like other mines, with a fusee.

The word is French. M. Huet derives it from *foetus*, or *fovea*, *fire*.

FOUL, in the *Sea-language*, is used when a ship has been long untrimmed, so that grass, weeds, periwinkles, barnacles, or the like, stick or grow to her sides under water. In this state, she is said to be *foul*.

A ship is said to make *fool water*, when, being under sail, she comes into such shoal, or low water, that though her keel doth not touch the ground, yet she comes so near it, that the motion of the water under her raises the mud from the bottom, and so *fools* the water.

FOUL is also a sea term, importing the running of one ship against another. This happens sometimes by the ungovernable violence of the wind, and sometimes by the carelessness of the people on board; and sometimes happens to ships of the same company; sometimes to such as meet accidentally; and sometimes to such as are in port, by means of others coming in. The damages occasioned by running *fool*, are of the nature of those in which both parties must bear a part; they are usually made half to fall upon the sufferer, and half upon the vessel which did the injury; but in cases where it is evidently the fault of the master of the vessel, he alone is to bear the damage.

FOUL ground of a road, bay, sea-coast, or harbour, signifies that which is rocky, or abounding with shallows, or otherwise dangerous.

FOUL buoy denotes that the cables are turned round each other, by the winding or turning about of a ship while the rides at anchor.

FOUL wind expresses that which is unfavourable, or contrary to the course of the ship, in opposition to large or fair.

FOUL feeding, in the *Monte*, denotes a voracious appetite, to which some horses are subject, which, though not properly a disease, is the cause of various maladies. It is commonly the effect of some latent distemper, and frequently occasioned by worms irritating the intestines. *Foul feeders* will leave their hay to eat their litter, even when it is soaked with their dung and urine, and discover a voracity as well as a voracious appetite. The best remedy in cases of this kind is to begin with purging, and to dissolve chalk in their water, and afterwards to give them good exercise. The following draught will also serve to blunt their appetites: take a large handful of the roots of marshmallows; cummin seeds, and fennel seeds, of each an ounce; liquorice roots sliced, half an ounce; boil them in three pints of water, till the roots are soft and slimy; then pour off the decoction, and dissolve in it an ounce of gum arabic, and add four ounces of linseed oil. Let the horse have four handfuls

of this mixture every morning fasting, till his appetite abates. Care should also be taken to keep the stalls as clean as possible. Gibbon's Farriery.

FOULDAGE. See **FALDAGE**.

FOULNESS of colour, in *Painting*, is used in opposition to brightness, and denotes a defect of purity. It is sometimes called *breaking* the colour.

FOULNESS in wounds. When what the surgeon calls uncleanliness or *foulness* is perceived in a wound, that is, when the flesh in it looks fungous, black, putrid, or livid, it must be well cleansed before any attempts are made to heal it. Different methods of cleansing this have been in use at different times among the surgeons; the ancients used honey, but the most usual practice now is, to apply a digestive ointment made of turpentine dissolved in the yolk of an egg, and afterwards mixed with honey of roses; but where this is not found strong enough for the purpose, the Egyptian ointment is to be used, mixed either with spirit of wine, or with the common digestive. To these digestive ointments a small quantity of aloes and myrrh may also very properly be added; and where more strength is required in them, a small quantity of red precipitate is to be added. The use of lime-water as a detergent is also very great, and yet more so, if there be added to every pint of it twenty or thirty grains of sublimate; this makes what is called the **PHAGEDENIC water**. Applications of this kind are to be continued till the wound is entirely clean, and then it is to be healed with the common digestives, &c. Heister's Surgery, p. 42.

FOUMART, a name used in some parts of England for the wheasel, called also, in some places, the *failet*. See **POLE-cat**.

FOUNDATION, that part of a building which is underground; or, that mass of stone, &c. which supports a building; or upon which the walls of the superstructure are raised; or, it is the coffer, or bed, dug below the level of the ground, to raise a building upon.

The *foundation* either takes up the whole area and extent of the building, as when there are to be vaults, cellars, or the like; or it is drawn in cuts, or trenches, as when only walls are to be raised.

The *foundation* is properly so much of the masonry, as reaches as high as the surface of the ground; and this is always to be proportioned to the load or weight of the building which it is to bear.

Sometimes it is massive, and continued under the whole building; as in the antique arches, and aqueducts, and some amphitheatres: more usually it is only in spaces, or intervals; either to avoid expence, or because the vaults are at too great a distance; in which latter case they make use of insulated pillars, bound together by arches. That we may find our habitation firmly, says Sir H. Wotton, we must first examine the bed of earth, upon which we are to build; and then the under-ceilings, or substruction, as the ancients called it. For the former we have the general precept in Vitruvius: *Solidioribus fundamentis solidantur, si quærent inveniuntur, & in solidis*: by which he recommends not only a diligent, but even jealous examination of what the soil will bear; advising us not to rest upon any appearing solidity, unless the whole mould, through which we cut, have likewise been solid.

But how deep we should go in this search, he has nowhere determined, as perhaps depending more on discretion than regularity, according to the weight of the work: yet Palladio has ventured to reduce it to a rule; allowing for the cavassone, i. e. the following or under-digging, a sixth part of the height of the whole fabric, unless there be cellars underground, in which case he would have it somewhat lower.

The *foundations* of buildings are either *natural* or *artificial*. *Natural*, as when we build on a rock, or a very solid earth; in which case we need not seek for any further strengthening. *Artificial*, where the ground is sandy, or marshy, or has lately been dug. In the former case, the architect must adjust the depth of the *foundation* by the height, weight, &c. of the building; a sixth part of the whole height is looked on as a medium; and as to thickness, double that of the width of the wall, is a good rule. Architects ought to use the utmost diligence in regard to *foundations*, since of all errors which may happen in building, an error in this point is most pernicious.

The ground fit for building upon is of various kinds; sometimes it is so hard as scarce to be cut with iron; in other places it is stiff, blackish, or whitish. This last is reckoned the weakest; and, in general, that is the best which requires most labour in cutting or digging.

When the ground is very bad, you must get large oaken piles of such a length as may reach the sound ground, and whose diameter must be about one twelfth part of their length: these must be driven down with a maul, and

as close to one another as possible, and that under the middle walls as well as the outer ones; and upon their tops large planks are to be pinned down. But if the ground be only faulty in some places, arches may be turned over them, by which means no part of the weight of the building will rest upon them.

As to the rules necessary to be observed in constructing the ground-work, they are these: 1. That the bottom of the trench be made exactly level. 2. That the lowest ledge or row be all of stone, laid close together. 3. That the breadth of the ground-work be at least double that of the wall that is to be raised on it. However, art ought always to give way to discretion, for the breadth may be regulated according to the goodness of the ground, and the weight of the intended edifice. 4. That the *foundation* be made to diminish as it rises, only care must be taken that it do so equally on both sides. 5. That you ought never to build upon the ruins of an old *foundation*, unless well assured of its depth and goodness.

In some places they found the pieces of bridges, and other buildings near the water, on facks of wool, laid like mattresses, which, being well pressed, and greasy, will never give way; nor rot in water. See BRIDGE, CAISSON, and COFFER-DAM.

FOUNDATION is also used figuratively for the establishment of a city, empire, or the like.

The Romans reckoned their years from the *foundation* of Rome, *ab urbe condita*; which we sometimes express by *ab U. C.* Chronologists make 745 years from the *foundation* of Egypt, to the *foundation* of Rome.

FOUNDATION also denotes a donation, or legacy, either in money, or lands, for the maintenance and support of some community, hospital, school, lecture, or other work of piety.

Among the order of Augustines, there is a *foundation* for the marrying of poor maids; and another for the furnishing of trusses to poor people who have ruptures, or hernias.

The founding and building of a college or hospital, is called *foundation*, *quasi fundatio*, or *fundamentum incans.* Ca. lib. 10. The king only can found a college; but there may be a college in reputation founded by others. *Dyer* 267. See **FOUNDER**.

FOUNDARY, in *Metalurgy*, a term used by the workers at the iron-mines, in many counties of England, for the space of six days, in which time they contrive to make a determinate quantity of iron, so that they count their work by their *foundary*, or weeks.

FOUNDER, he who lays a foundation, or who *founds* and endows a church, school, religious house, or other work of charity and piety.

The *founders* of churches may preferre to themselves the right of patronage, or presentation to the living. The *founder* of all corporations in the strictest and original sense is the king alone, for he only can incorporate a society; and in civil incorporations, such as Mayor and Commonalty, &c. where there are no possessions or endowments given to the body, there is no other *founder* but the king; but in eleemosynary foundations, such as colleges and hospitals, where there is an endowment of lands, the law distinguishes, and makes two species of foundation; the one *fundatus incipiens*, or the incorporation, in which sense the king is the general *founder* of all colleges and hospitals; the other *fundatus perfectus*, or the donation of it; in which sense the first gift of the revenues is the foundation, and he who gives them is in law the *founder*; but if the king and a private person join in endowing an eleemosynary foundation, the king alone shall be the *founder* of it.

FOUNDER is also an artist that melts or casts metals into various forms, for divers uses; as guns, bells, statues, bombs, types, or printing characters; and other small works, as candlesticks, buckles, &c.

The word in this sense is formed of the French *fonder*, to melt or fuse. In the Roman law they are called *fundarii*.

From the different professions, or works of the *founders*, they are differently denominated, as *founders of small works*; *bell-founders*; *gun-founders*; *letter-founders*; *figure-casters*, &c. What belongs to each, see under **FOUNDER**.

FOUNDER, in *Glass-making*, is a term appropriated to the green-glass houses, and is the person there, who in the same office in the white-glass-making is called the *CONCIATOR*.

FOUNDER'S FURNACE. See **FURNACE**.

FOUNDERS, moulds of. See **MOULDS**.

FOUNDER'S PRILL. See **PRESS**.

FOUNDER, in the *Sea-language*. A ship is said to *founder* at sea, when by an extraordinary leak, or a great sea breaking in upon her, she is so filled with water, that she cannot be freed of it, nor is able to swim under it, but sinks with the weight thereof.

FOUNDERING, in the *Manège*, a disorder in horses, whereof there are two kinds, viz. in the feet, and in the chest.

FOUNDERING in the feet, arises from hard riding, severe labour, great heats, sudden colds, &c. which inflame the blood, and, as the farriers term it, melt the grease, and make it descend downward to the feet, and there settle; which causes such numbness, and pricking in the hoofs, that the horse has no sense of feeling in it, being hardly able to stand; or, when he does, shaking and trembling as if he had an ague.

A horse may likewise be *foundered*, by wearing straight shoes, and by travelling upon hard ground.

It may be known when he is *foundered* on his fore-feet, and not his hind feet, by his treading firmly on his hind-feet, and sparing the other; or his going crouching or crippling on his buttocks.

Sometimes, though rarely, he is *foundered* in his hind-feet, and not his fore; which is known by his seeming weak behind; and resting, as much as possible, on the fore-feet.

The general methods of curing this disorder are, first, by paring all the horse's soles to thin, that the quick may be seen; then bleeding him well at the toes; stopping the vein with tallow and resin; and then, having raked hollow shoes on his feet, stopping them with bran, tar, and tallow, as boiling hot as may be; which is to be renewed once in two days, for a week together; after which he is to have good exercise.

Or, after he is pared thin, and let blood at the toes, his feet are to be stopped with cows-dung, kitchen-fee, tar, and foot, boiled together, and poured, boiling hot, into them.

FOUNDERING in the chest, or body, usually befalls a horse by eating too much provender suddenly, when too hot; or also by drinking too much upon travelling, when he is hot, and riding him after it.

The effect of which is, that the body is oppressed with ill humours, which take away his strength, and put him in such condition, that he can neither go, nor bow his joints; and, being once laid, he cannot rise again, &c. his legs swell; and, soon after begin to peel; he has a dry cough, which makes his eyes water; and his nose runs with white phlegmatic matter. For the cure of this disorder, take five or six pennyworth of oil of pure and mingle it with an equal quantity of ale or beer; then rub this mixture with the hand on the part affected and at the same time hold a red hot shovel before it.

FOUNDERY, or **FOUNDRY**, the art of melting and casting all sorts of metals; particularly brass, iron, bell metal, &c. The word is also used for a place, or workshop, furnished with furnaces, or forges for this purpose.

FOUNDERY of small works, or the manner of **CASTING** is said.

The first used by the founders, in casting brass, &c. is yellowish, and pretty soft; but, after it has been used, it becomes quite black, because of the charcoal-dust fixed in the moulds. Every time they would use this sand, they work and tow it, several times over, in a board about a foot square, placed over a kind of trunk, or box, into which it may fall from off the board. This tewing is performed with a roller, or cylinder, about two feet long, and two inches in diameter; and a kind of knife, made of the blade of a sword: with the two instruments they alternately roll and cut the sand; and, at length, turn it down into the box or trough underneath.

Then, taking a wooden board, or table, of a length and breadth proportional to the quantity of things to be cast; round this they put a frame or ledge; and thus make a sort of mould. This mould they fill with the sand before prepared, and moderately moistened: which done, they take wooden, or metalline models, or patterns of the things intended to be cast; apply them on the mould, and press them down in the sand, so as to leave their form indented; along the middle of the mould is laid half a little cylinder of brass, which is to be the master-jet, or canal for running the metal; being so disposed, as to touch the ledge on one side, and only to reach to the last pattern on the other: from this are placed several lesser jets, or branches, reaching to each pattern, whereby this metal is conveyed through the whole frame.

This first frame being thus finished, they turn it upside down, to take out the patterns from the sand; in order to which, they first loosen them a little all round, with a small cutting instrument.

After the same manner they proceed to work the counter-part, or other half of the mould, with the same patterns, in a frame exactly like the former; excepting that it has pins, which, entering holes corresponding thereto in the other, make, when the two are joined together, the two cavities of the pattern fall exactly on each other.

The frame, being thus moulded, is carried to the founder, or melter; who, after enlarging the principal jet, or canal, of the counter-part, with a kind of knife, adding

he casts jets, or canals, to the several patterns in both, and sprinkling them over with mill-dust, sets them to dry in an oven.

When both parts of the mould are sufficiently dried, they join them together, by means of the pins; and, to prevent their flaking, or slipping aside, by the force of the metal, which is to come in flaming hot, through a hole contrived at the master jet, they lock them in a kind of press, either with screws; or, if the mould be too big for this, with wedges. The moulds, thus put in the press, are ranged near the furnace, to be in readiness to receive the metal as it comes out of the crucible.

While the moulds are thus preparing, the metal is put in fusion in an earthen crucible, about ten inches high, and four in diameter.

The furnace wherein the fusion is made, is much like the smith's forge; having, like that, a chimney, to carry off the smoke; a pair of bellows to blow up the fire; and a hearth where the fire is made, and the crucible placed. It is the use of this hearth, that chiefly distinguishes the furnace from the forge.

In the middle thereof is a square cavity, ten or twelve inches wide, which goes to the very bottom: it is divided into two, by an iron grate: the upper partition serves to hold the crucible, and the fuel; and the lower to receive the ashes.

When the fuel, which is to be of dry wood, is pretty well lighted, they put the crucible full of metal in the middle, and cover it with an earthen lid; and, to increase the force of the fire, besides blowing it up with the bellows, they lay a tile over part of the aperture or cavity of the furnace.

The metal first put in being brought to a fusion, they fill the crucible with pieces of brass beaten in a mortar; to put them in they make use of a kind of iron ladle, with a long spout at the end thereof, formed into a kind of hollow cylinder, out of which the piece is dropped. Nothing now remains, but for the founder to take the crucible out of the fire, and carry it in a pair of iron tongs (whose feet are bent, the better to embrace the top of the crucible), to the mould; into which he pours the melted metal, through the hole answering to the master-jet of each mould.

Thus he goes successively, from one to another, till his crucible is emptied, or there is not matter enough left for another mould.

Then, casting cold water on the moulds, they take the frames out of the presses, and the castworks out of the sand: which afterwards they work again, for another casting. Lastly, they cut off the jets, or casts, and sell or deliver the work to those who bespoke it, without any farther repairing.

FOUNDRY of statues, great guns, and bells. The art of casting statues in brass is very ancient; inasmuch that its origin was too remote and obscure, even for the research of Piny; an author admirably skilled at discovering the inventors of other arts.

All we can learn for certain, is, that it was practised, in all its perfection, first among the Greeks; and afterwards, among the Romans; and that the number of their statues consecrated to their gods and heroes surpassed all belief. See **STATUE**.

The single cities of Athens, Delphos, Rhodes, &c. had each three thousand statues; and Marcus Scaurus alone, though only exile, adorned the circus with no less than three thousand statues of brass, for the time of the Circensian games. This taste for statues was finally carried to such a pitch, that it became a proverb, that in Rome the people of brass were not less numerous than the Roman people.

Among us, the casting of statues was but little known, or practised, before the seventeenth century.

As to the casting of guns, it is quite modern; and it were, perhaps, to be wished, we were as ignorant of it as the ancients. All authors agree, that the first cannon were cast in the fourteenth century; though some ascribe the event to the year 1338, and others to 1380. See **CANNON** and **GUNNARY**.

The casting of bells is of a middle standing, between the other two. The use of bells is certainly very ancient in the western church; and the same were likewise once used in the church of the East. But, at present, F. Vansleb assures us, in his second account of Egypt, he had found but one bell in all the eastern church, and that in a monastery in the Upper Egypt. See **BELL**.

The matter of these large works is rarely any simple metal, but commonly a mixture of several. We shall here give the process in the foundry of each.

Method of casting statues, or figures. See **BRONZE**. There are three things chiefly required in casting of statues, busts, bas-reliefs, vases, and other works of sculpture: viz. the mould, the wax, and shell, or coat.

The inner mould, or core (thus called from *corer*, as being in the heart or middle of the statue,) is a rude lumpish figure, to which is given the attitudes and contours of the statue intended: it is raised on an iron grate, strong enough to sustain it; and is strengthened withinside by several bars, or ribs, of iron.

It may be made at the discretion of the workmen; of potters clay, mixed up with horse-dung and hair; or of plaster of Paris, mixed with fine brickdust.

The use of the core in statues is to support the wax and shell, to lessen the weight and to save metal. In bells it takes up all the inside, and preserves the space vacant where the clapper is hung. In great guns it forms the whole chase, from the mouth to the breech: and, in mortars, the chase, and chamber. The iron bars and the core are taken out of the brass figure, through an aperture left in it, which is afterwards soldered up: but it is necessary to leave some of the iron bars of the core that contribute to the steadiness of the projecting parts, within the brass figure.

The wax is a representation of the intended statue. If it be a piece of sculpture, the wax must be all of the sculptor's own hand, who usually fashions it on the core itself, though it may be wrought separately, in cavities, moulded, or formed, on a model, and afterwards disposed and arranged on the ribs of iron over the grate, as before; filling the vacant space in the middle with liquid plaster, and brick-dust; by which means the inner mould, or core, is formed in proportion as the sculpture carries on the wax.

When the wax (which is to be of the intended thickness of the metal) is finished, they fix little waxen tubes perpendicularly to it, from top to bottom: to serve, both as jets, for the conveyance of the metal to all parts of the work; and as vent-holes, to give passage to the air, which would, otherwise, occasion great disorder, when the hot metal came to encompass it. By the weight of the wax used herein, is that of the metal adjusted; ten pounds of this last being the proportion to one pound of the former. The work brought thus far, wants nothing but to be covered with its shell; which is a kind of coat, or crust, laid over the wax; and which, being of a soft matter, and even, at first, liquid, easily takes and preserves the impression of every part thereof; which it afterwards communicates to the metal, upon its taking the place of the wax, between the shell and the core. The matter of this outer mould, or shell, is varied according as different layers, or strata, are applied. The first is a composition of clay, and old white crucibles, well ground and sifted, and mixed up with water, to the consistence of a colour fit for painting: accordingly, they apply it with a pencil, laying it seven or eight times over, letting it dry between whiles. For the second impression, they add horses dung and natural earth to the former composition. The third impression is only horses dung and earth. Lastly, the shell is finished by laying on several more impressions of this last matter, made very thick with the hand.

The shell, thus finished, is secured and strengthened by several bands, or girths, of iron, wound around it at half a foot's distance from one another, and fastened at bottom to the grate under the statue; and at the top to a circle of iron, where they all terminate.

Here it must be observed, that if the statue be so big, that it would not be easy to move the moulds, when thus provided, it must be wrought on the spot where it is to be cast.

This is performed two ways; in the first, a square hole is dug under-ground, much bigger than the mould to be made therein, and its inside lined with walls of freestone, or brick. At the bottom is made a hole, of the same materials, with a kind of furnace, having its aperture outwards: in this is a fire to be lighted, to dry the mould; and, afterwards, to melt the wax. Over this furnace is placed the grate; and on this the mould, &c. framed as above explained. Lastly, at one of the edges of the square pit is made another large furnace, to melt the metal, as hereafter mentioned.

In the other way, it is sufficient to work the mould above-ground; but with the same precaution of a furnace, and grate, underneath: when finished, four walls are to be run up round it: and, by the side thereof, a massive made, for a melting furnace. For the rest, the method is the same in both. The mould being finished, and enclosed between four walls, whether under-ground, or above it, a moderate fire is lighted in the furnace under it, and the hole covered with planks, that the wax may melt gently down, and run out at pipes contrived for the purpose, at the foot of the mould; which are afterwards very exactly closed with earth, as soon as all the wax is carried off.

This done, the hole is filled up with bricks thrown in at random, and the fire in the furnace is augmented till such

time as both the bricks and the mould become red-hot; which ordinarily happens in twenty-four hours. Then, the fire being extinguished, and every thing cold again, they take out the bricks, and fill up their place with earth, moistened, and a little beaten, to the top of the mould, in order to make it the more firm and steady.

Things being in this condition, there remains nothing but to melt the metal, and run it into the mould: this is the office of the furnace above, which is made in manner of an oven, with three apertures; one to put in the wood; another for a vent; and a third to run the metal out at. From this last aperture, which is kept very close whilst the metal is in fusion, a little tube or canal is laid, whereby the melted metal is conveyed into a large earthen basin over the mould; into the bottom of which all the big branches of the jets, or canals, which are to carry the metal into all the parts of the mould, are inserted.

It must be added, that these jets are all terminated, or stopped with a kind of plug, which are kept close, that upon opening the furnace, the brass which gushes out like a torrent of fire, may not enter any of them till the basin be full enough of matter to run into them: all at once, upon which occasion they pull out the plugs, which are long iron rods, with a head at one end, capable of filling the whole diameter of each tube. The hole of the furnace is opened with a long piece of iron, fixed at the end of a pole; and the mould is then filled in an instant.

The work is now finished, at least so much as belongs to the casting, the rest being the sculptor's, or carver's business; who, taking the figure out of the mould and earth with which it is encompassed, fixes the jets, where with it appears covered over, and repairs it, with instruments proper to his art, as chisels, gravers, punchtools, &c.

FOUNDRY. *The manner of casting bells.* What has been hitherto shown of the casting of statues, holds, in proportion of the casting of bells; that which is particular in these latter, is as follows: first, being the metal is different, there being no tin in the metal of statues, but no less than a fifth part of tin in that of bells. Secondly, the dimensions of the crown, and the wax of bells, especially if it be a ring of several bells that is to be cast, are not left to chance, or the caprice of the workman, but must be measured, on a kind of scale, or DIAPASON, which gives the height, aperture, and thickness, necessary for the several tones required.

It need not be added, that it is on the wax, that the several mouldings and other ornaments, and inscriptions, to be represented in relief, on the outside of the bell, are formed. The clapper, or tongue, is not properly a part of the bell, but is furnished from other hands. In Europe, it is usually of iron, with a large knob at the extreme; and is suspended in the middle of the bell. In China, it is only a huge wooden mallet, struck by force of arm against the bell; whence they can have but little of that consonance so much admired in some of our rings of bells. The Chinese have an extraordinary way of increasing the found of their bells; viz. by leaving a hole under the cannon; which our bell founders would reckon a defect.

The proportions of our bells differ very much from those of the Chinese. In ours, the modern proportions are, to make the diameter fifteen times the thickness of the brim, and the height twelve times. The parts of a bell are 1. the founding bow, terminated by an inferior circle, which grows thinner and thinner. 2. The brim or that part of a bell whereon the clapper strikes, and which is thicker than the rest. 3. The outward flaring of the middle of the bell, or the point under which it grows wider to the brim. 4. The waist or furniture, and the part that grows wider and thicker quite to the brim. 5. The upper vane, or that part which is above the waist. 6. The pallet which supports the staple of the clapper within. 7. The bent and hollowed branches of metal uniting with the cannons, to receive the iron keys, whereby the bell is hung up to the beam which is its support and counterpoise, when rung out. The business of bell-foundry is reducible to three particulars. 1. The proportion of a bell. 2. The forming of a mould. And, 3. the melting of the metal. There are two kinds of proportions, viz. the simple and the relative; the former are those proportions only that are between the several parts of a bell to render it sonorous; the relative proportions establish a greater harmony between several bells. The method of forming the profile of a bell, previous to its being cast, in which the proportion of the several parts may be seen, is as follows: the thickness of the brim, Ci (See *Tak. Measur.* p. 13.) is the foundation of every other measure, and is divided into three equal

parts. First, draw the line HD , which represents the diameter of the bell; bisect it in F , and erect the perpendicular Ff ; let DE and HF be also bisected in E and G ; GE will be the diameter of the top or upper vane; E the diameter of the top will be half that of the bell; and it will, therefore, be the diameter of a bell which will found an octave to the other. Divide the diameter of the bell, or the line HD into fifteen equal parts, and one of these will give Ci the thickness of the brim; divide again each of these fifteen equal parts into three other equal parts, and then form a scale. From this scale take twelve of the larger divisions or $\frac{2}{3}$ of the whole scale in the compass, and setting one leg in D , describe an arc to cut the line DE in N , draw ND , and divide this line into twelve equal parts; at the point i erect the perpendicular $iC = 10$, and Ci will be the thickness of the brim $= \frac{2}{3}$ of the diameter. draw the line CD ; bisect DN and at the point of bisection o erect the perpendicular $oK = 14$ of the larger divisions on the scale. With an opening of the compass equal to twice the length of the scale or thirty brims, letting one leg in N , describe an arc of a circle, and with the same leg in i , and the same opening describe another arc to intersect the former; on this point of intersection, as a centre, and with a radius equal to thirty brims, describe the arc NK_2 ; in oK produced take $Ki = \frac{2}{3}$ of the larger measure of the scale, or $\frac{2}{3}$ of the brim, and on the same centre with the radius $30\frac{2}{3}$ brims describe an arc AB parallel to NK . For the arc BC , take twelve divisions of the scale, or twelve brims in the compass, find a centre, and from that centre, with this opening describe the arc BC in the same manner as NK or AB were described. There are various ways of describing the arc Kp_3 some describe it on a centre at the distance of nine brims from the points p and K ; others, as it is done in the figure, on a centre at the distance only of seven brims from those points. But it is necessary first to find the point ip , and to determine the rounding of the bell p_3 . For this purpose, on the point C as a centre and with the radius Ci describe the arc p_2 ; bisect the part 3 , 2 of the line DE , and erecting the perpendicular pm , this perpendicular will cut the arc p_2 in m , which terminates the rounding ip . Some founders make the bounding K_2 a third of a brim lower than the middle of the line DN ; others make the part C_2D more acute, and instead of making C_2 perpendicular to DN at i , draw it $\frac{1}{3}$ of a brim higher, making it still equal to one brim, so that the line iD is longer than the brim Ci . In order to trace out the top-part N_2 , take in the compass eight divisions of the scale or eight brims, and on the points N and D , as centres, describe arcs to intersect each other in 8_2 ; on this point 8_2 with a radius of eight brims, describe the arc N_2 ; this arc will be the exterior curve of the top or crown, on the same point 8_2 as a centre and with a radius equal to $7\frac{1}{2}$ brims, describe the arc AB , and this will be the interior curve of the crown, and its whole thickness will be one third of the brim. As the point 8 does not fall in the axis of the bell, a centre M may be found in the axis by describing with the interval of eight brims on the centres D and H arcs which will intersect in M ; and this point may be made the centre of the inner and outer curves of the crown, as before. The thickness of the esp, which strengthens the crown at Q , is about one third of the thickness of the brim; and the hollow branches or ears about one fifth of the diameter of the bell. The height of the bell is in proportion to its diameter, as twelve to fifteen, or in the proportion of the fundamental found to its third major; whence it follows, that the found of a bell is principally composed of the found of its extremity or brim, as a fundamental, of the found of the crown which is an octave to it, and of that of the height which is a third. *Euryclipeode, Art. Cloche.* See *BELL*.

The particulars necessary for making the mould of a bell, are, 1. The earth: the most cohesive is the best; it must be well ground and sifted, to prevent any clumps. 2. Brick-stone, which must be used for the mine, mould, or core, and for the furnace. 3. Horse-dung, hair, and hemp, mixed with the earth, to render the cement more binding. 4. The wax for inscriptions, coats of arms, &c. 5. The tallow equally mixed with the wax, in order to put a slight lay of it upon the outer mould, before any letters are applied to it. 6. The coals to dry the mould.

For making the mould, they have a scaffold consisting of four boards, ranged upon tripods. Upon this they carry the earth, grossly diluted, to mix it with horse-dung, beating the whole with a large spatula.

The compasses of construction are the chief instrument for making the mould, which consist of two different legs, joined by a third piece. And last of all, the founders

themselves, on which are the engravings of the letters, carriages, coats of arms, &c.

They first dig a hole of a sufficient depth to contain the mould of the bell, together with the case, or cannon, under ground; and about six inches lower than the surface, where the work is performed. The hole must be wide enough for a free passage between the mould and walls of the hole; or between one mould and another, when several bells are to be cast. At the centre of the hole is a stake erected, that is strongly fastened in the ground. This supports an iron-peg, on which the pivot of the second branch of the compass turns. The stake is encompassed with a solid brick-work, perfectly round, about half a foot high, and of the proposed bell's diameter. This they call a mill-stone. The parts of the mould are the core, the model of the bell, and the shell. When the outer surface of the core is formed, they begin to raise the core, which is made of bricks that are laid in courses, of equal height, upon a bed of plain earth. At the laying of each brick, they bring near the bell branch of the compass, on which the curve of the core is shaped, so as that there may remain between it and the curve the distance of a line, to be afterwards filled up with layers of cement. The work is continued to the top, only leaving an opening for the coils to blow the wax. This work is covered with a layer of cement, made of earth and bo-f-dung, on which they move the compasses of contrivance, to make it of an even smoothness every where.

The first layer being finished, they put the fire to the core, by filling it half with coals, through an opening that is kept shut, during the baking, with a cake of earth, that has been separately baked. The first fire consumes the stake, and the fire is left in the core half, or, sometimes, a whole day: the first layer being thoroughly dry, they cover it with a second, third, and fourth; each being smoothed by the board of the compass, and thoroughly dried before they proceed to another.

The core being completed, they take the compasses to pieces with intent to cut off the thickness of the model, and the compasses are immediately put in their place, to begin a second piece of the mould. It consists of a mixture of earth and hair, applied with the hand on the core, in several cakes that close together. This work is finished by several layers of a thinner cement of the same matter, smoothed by the compasses, and thoroughly dried, before another is laid on. The last layer of the model is a mixture of wax and grease spread over the whole. After which are applied the interpositions, coats of arms, &c. delineated with a pencil dipped in a vessel of wax on a chalking-dish: this is done for every letter. Before the shell is begun, the compasses are taken to pieces, to cut off all the wood that fills the place of the thickness to be given to the shell.

The first layer is the same earth with the rest, sifted very fine; which it is tempering in water, it is mixed with cow's hair, to make it cohere. The whole being a thin cullis, is gently poured on the model, that fills exactly all the inequalities of the figures, &c. and this is repeated till the whole is two lines thick over the model. When this layer is thoroughly dried, they cover it with a second of the same matter, but something thicker: when this second layer becomes of some consistency, they apply the compasses again, and light a fire in the core, so as to melt off the wax of the interpositions, &c.

After this they go on with other layers of the shell, by means of the compasses. Here they add to the cow's hair a quantity of hemp, forced upon the layers, and afterwards smoothed by the board of the compasses. The thickness of the shell comes to four or five inches lower than the mill-stone before observed, and surrounds it quite close, which prevents the extravasation of the metal. The wax should be taken out before the melting of the metal.

The ear of the bell requires a separate work, which is done during the drying of the several incrustations of the cement. It has seven rings, the seventh is called the bridge, and unites the others, being a perpendicular support to strengthen the curves. It has an aperture at the top, to admit a large trumpet, bent at the bottom; and this is introduced into two holes in the beam, filled with two strong iron-eyes. These are models made of the rings, with masses of beaten earth, that are dried in the fire, in order to have the hollow of them. These rings are gently pressed upon a layer of earth and cow's hair, one half of its depth; and then taken out, without breaking the mould. This operation is repeated twelve times for twelve half-models, that two and two united may make the hollow of the six rings: the same they do for the hollow of the bridge, and bake them all, to unite them together.

Upon the open place left for the coils to be put in, are placed the rings that constitute the ear. They first put into this open place the iron-ring to support the clapper of the bell; then they make a round cake of clay, to fill up the diameter of the thickness of the core. This cake, after baking, is clapped upon the opening, and soldered with a thin mortar spread over it, which binds the core close to the core.

The hollow of the model is filled with an earth, furnished moist, to lie on the place, which is strewn, at several times, upon the cover of the core; and they beat it gently with a pello, to a proper height; and a workman smooths the earth at top with a wooden trowel dipped in water.

Upon this cover, to be taken off afterwards, they assemble the hollows of the rings. When every thing is in its proper place, they strengthen the outside of the hollows with mortar, in order to bind them with the bridge, and keep them steady at the bottom, by means of a cake of the same mortar, which fills up the whole aperture of the shell. This they let dry, that it may be removed without breaking, to make room for the metal they pull off the hollows of the rings, through which the metal is to pass, before it enters into the cavity of the mould. The shell being unloaded of its ear, they range under the mill-stone five or six pieces of wood, about two feet long, and thick enough to reach almost the lower part of the shell; between these and the mould they drive in wooden wedges with a mallet, to shake the shell of the model wherein it rests, so as to be pulled up, and got out of the pit.

When this and the wax are removed, they break the model and layer of earth, through which the metal must run, from the hollow of the rings, between the bell and the core. They smoke the inside of the shell, by burning straw under it, that helps to smooth the surface of the bell. Then they put the shell in the place, so as to leave the same interval between that and the core; and before the hollows of the rings or the cap are put on again, they add two vents, that are united to the rings, and to each other, by a mass of baked cement. After which they put on this mass of the cap, the rings, and vents, over the shell, and solder it with thin cement, which is dried gradually by covering it with burning coals. Then they fill up the pit with earth, beating it thoroughly all the time round the mould.

The furnace has a place for the fire, and another for the metal. The fire place has a large chimney, with a spacious ash-hole: the furnace which contains the metal is vaulted, whose bottom is made of earth, rammed down; the rest is built with brick. It has four apertures; the first, through which the flame reverberates; the second is closed with a stopple, that is opened for the metal to run; the others are to separate the dross, or scum, of the metal by wooden rakes; through these last apertures passes the thick smoke. The ground of the furnace is built sloping, for the metal to run down. See Dict. Commerce. Eng. edit. art. FOUNDRY.

FOUNDRY. *Manner of casting great guns, or pieces of artillery.* The casting of cannons, mortars, and other pieces of artillery, is performed much like that of statues, and bells; especially as to what regards the wax, shell, and furnaces.

All pieces of artillery are now cast solid, and bored afterwards by means of a machine invented at Stralburgh, (see *Boring of Cannon*) and much improved by Mr. Verbruggen, the present head-founder at Woolwich. The gun to be bored was at first placed in a perpendicular position; but the machines used for this purpose have lately been made to bore horizontally, and much more exactly than those that bore in a vertical situation. Whilst the inside is bored, the outside is turned and polished at the same time.

As to the metal it is somewhat different from both; as having a mixture of tin, which is not in that of statues; and only having half the quantity of tin that is in bells, i. e. at the rate of ten pound of tin to a hundred of copper. The respective quantities of different metals that should enter into the composition for brass cannon is not absolutely decided; the most common proportions of the ingredients are the following, viz. to 240 lb of metal fit for casting, they put 68 lb of copper, 52 lb of brass, and 12 lb of tin. To 4200 lb of metal fit for casting, the Germans put 3687 lb of copper, 3042 lb of brass, and 3072 lb of tin. Others, again, use 100 lb of copper, 6 lb of brass, and 9 lb of tin; and lastly, others make use of 100 lb of copper, 10 lb of brass, and 15 lb of tin. See CANNON.

A cannon is always shaped a little conical, being thickest of metal at the breech, where the greatest effort of the gunpowder is made, and diminishing thence to the muzzle.

ele; so that if the mouth be two inches thick of metal, the teeth is six. See CANNON.

Its length is measured in calibers, i. e. in diameters of the muzzle. Six inches at the muzzle require twenty calibers, or ten feet in length; there is always about the six-h of an inch allowed play for the ball. For the parts, and their respective proportions of different fortifications, see CANNON and GUN. The method of casting iron cannon differs very little from that of brass.

FOUNDERY, Letter, or the manner of setting printing letters. The invention of printing letters we shall speak of under PRINTING and LETTER.

Their differences, kind, &c. have already been explained under the article CHARACTER, &c.

In the business of cutting, casting, &c. letters for printing, the letter-cutter must be provided with a vice, hand-vice, hammers and files of all sorts for witch-makers use; as also gravers and sculptors of all sorts, and awl-stone, &c. suitable and fixable to the several letters to be cut: a flat gage made of box to hold a rod of steel, or the body of a mould, &c. exactly perpendicular to the flat of the using-file: a sliding gage, whose use is to measure and set off distances between the shoulder and the tooth, and to mark it off from the end, or from the edge of the work; a face-gage, which is a square notch cut with a file into the edge of a thin plate of steel, iron, or brass, of the thickness of a piece of common tin, whose use is to proportion the face of each sort of letter, viz. long letters, ascending letters, and short letters. So there must be three gages, and the gage for the long letters is the length of the whole body supposed to be divided into forty-two equal parts. The gage for the ascending letters Roman and Italic are 2 or 30 parts of 42, and 32 parts for the English face. The gage for the short letters is 4 or 18 parts of 42 of the whole body for the Roman and Italic, and 24 parts for the English face.

The Italic and other hand-gages are to measure the scope of the Italic stems, by applying the top and bottom of the gage to the top and bottom lines of the letters, and the other side of the gage to the stem; for when the letter complies with these three sides of the gage, that letter has its true shape.

The next care of the letter-cutter is to prepare good steel punches, well temper, and quire free from all veins of iron; on the face of which he draws or marks the exact shape of the letter, with pen and ink, if the letter be large; or with a smooth blunted point of a needle, if it be small; and then with file and proper shaped and pointed gravers and sculptors, digs or sculps out the steel between the strokes or marks he made on the face of the punch, and leaves the marks standing on the face. Having well shaped the inside strokes of his letter, he deepens the hollows with the file tools: for if a letter be not deep in proportion to its width, it will, when used at press, print black, and be good for nothing. This work is generally regulated by the depth of the counter-punch. Then he works the outside with proper files till it be fit for the matrix.

But, before we proceed to the sinking and justifying of the matrices, we must provide a mould to justify them by, of which you have a draught in *Tat. Metallurg. fig. 13. 14.*

Every mould is composed of an upper and an under part. The under part is delineated in *fig. 13.* The upper part is marked *fig. 14.* and is in all respects made like the under part, excepting the foot behind, and the bow, or spring, also behind; and excepting a small roundish wire between the body and carriage, near the break where the under part hath a small rounding groove made in the body. This wire, or rather half-wire, in the upper part, makes the nick in the flank of the letter, when part of it is received into the groove in the under part. These two parts are to exactly fitted and gaged into one another (viz. the male gage, marked *c* in *fig. 14.* into the female marked *g* in *fig. 13.*) that when the upper part of the mould is properly placed on, and in the under part of the mould, both together make the entire mould, and may be slid backwards for use so far, till the edge of either of the bodies on the middle of either carriage comes full to the edge of the female gage, cut in each carriage; and they may be slid forwards to far, till the bodies on either carriage touch each other: and the sliding of these two parts of the mould backwards makes the flank of the letter thicker, because the bodies in each part stand wider asunder, and the sliding them forwards makes the flank of the letter thinner, because the bodies on each part of the mould stand closer together. The parts of the mould are as follow: viz.

- a The carriage.
- b The body.
- c The male gage.

d e The mouth-piece.

f i The regular.

g The female gage.

h The bag.

a a a The bottom plate.

b b b The wood, on which the bottom plate lies.

c c c The mouth.

d d d The throat.

e e e The pallet.

f The nick.

g g The floor.

h h The spring or bow.

Then the mould must be justified: and first the foundry justifies the body, by casting about twenty proofs, or samples of letters: which are set up in a composing stick with all their nicks towards the right hand; and then by comparing these with the pattern letters, set up in the same manner, he finds the exact measure of the body to be cast. He also tries if the two sides of the body are parallel, or that the body be no bigger at the head than at the foot; by taking half the number of his proofs, and turning them with their heads to the feet of the other half; and if then the heads and the feet be found exactly even upon each other, and neither to drive out nor get in, the two sides may be pronounced parallel. He farther tries whether the two sides of the thickness of the letter be parallel by first setting his proofs in the composing stick with their nicks upwards; and then turning one half with their heads to the feet of the other half; and if the heads and feet lie exactly upon each other, and neither drive out nor get in, the two sides of the thickness are parallel.

The mould thus justified, the next business is to prepare the matrices. A matrix is a piece of brass or copper of about an inch and a half long, and of a thickness in proportion to the size of the letter it is to contain. In this metal is sunk the face of the letter intended to be cast, by striking the letter punch about the depth of an n. After this the sides and face of the matrix must be justified and cleared, with files, of all buncings made by sinking the punch.

Every thing thus prepared, it is brought to the furnace which is built of brick upright, with four square flues and a flue on the top, in which flue is a wide round hole for the pan to stand in. A foundry of any consequence has several of these furnaces in it.

As to the metal of which the types are to be cast, this, in extensive foundries, is always prepared in large quantities; but cast into small bars, of about twenty pounds weight, to be delivered out to the workmen as occasion requires. In the letter foundry which has been long carried on with reputation, under the direction of Dr. Alex. Wilson, and sons, at Glasgow, we are informed, that a flock of metal is made up at two different times of the year, sufficient to serve the callers at the furnace for six months each time. For this purpose a large furnace is built under a shade, furnished with a wheel vent, in order the more equally to heat the sides of a strong pot of cast iron which holds, when full, fifteen hundred weight of the metal. The fire being kindled below, the bars of lead are let fall down into the pot, and their fusion promoted by throwing in some pitch and tallow, which soon inflame. An outer chimney, which is built so as to project about a foot over the farthest lip of the pot, catches hold of the flame by a strong draught, and makes it act very powerfully in melting lead; whilst it serves at the same time to convey away all the fumes, &c. from the workmen, to whom this laborious part of the business is committed. When the lead is thoroughly melted, a due proportion of the regulus of antimony and other ingredients are put in, and some more tallow is inflamed, to make the whole incorporate sooner. The workmen now having mixed the contents of the pot very thoroughly, by stirring long with a large iron ladle, next proceed to draw the metal off into the small troughs of cast iron which are ranged, to the number of fourteen, upon a level platform, faced with stone, built towards the right hand. In the course of a day fifteen hundred weight of metal can be easily prepared in this manner; and the operation is continued for as many days as are necessary to prepare a flock of metal, of all the various degrees of hardness. After this the whole is disposed into presses, according to its quality, to be delivered out occasionally to the workmen.

The foundry must be now provided with a ladle, which differs nothing from other iron ladles, but in its size. And he is provided always with ladles of several sizes, which he uses according to the size of the letters he is to cast. Before the caster begins to cast, he must kindle his fire in the furnace to melt the metal in the pan. Therefore he takes the pan out of the hole in the flue, and there

there lays in coals and kindles them; and, when they are well kindled, he joss the pan in again and puts in metal into it to melt; if it be a small-bodied piece he calls, or a thin letter of great bodies, his metal must be very hot; may sometimes red-hot, to make the letter come. Then having choise a ladle that will hold about so much as the letter and break it, he lays it at the flowing-hole, when the flame bursts out, to heat. Then he fits a thin leather cut with his narrow and against the face to the leather groove of the matrix, by whipping a broken thread twice about the leather-groove, and fastening the thread with a knot. Then he puts both halves of the mould together, and puts the surface into the matrix, check, and places the foot of the matrix on the foot of the mould, and the broad end of the leather upon the wood of the upper half of the mould, but not tight up, lest it might hinder the foot of the matrix from sliding close down upon the flint in a train of work. Then laying a little rosin on the upper wood of the mould, as if having his callings, little hole, he with the bellows-side of it melts the rosin; and, when it is yet melted, pushes the broad end of the leather hard down on the wood, and so fastens it to the wood; all this is the preparation.

Now he comes to casting. Wherefore placing the upper half of the mould in his left hand, with the hook or fore force, he catches the end of the wood between the lower part of the ball of his thumb and his three hind fingers; then he lays the upper half of the mould upon the under half, so that the male pages may fall into the female pages, and at the same time the foot of the matrix places itself upon the foot; and, clasping his left hand through frame over the upper half of the mould, he nimble catches hold of the bow or spring with his right hand fingers at the top of it, and his thumb under it, and places the point of it against the middle of the notch in the backside of the matrix, pulling it as well forwards towards the mould, as downwards, by the shoulder of the notch close upon the foot, while at the same time with his hinder fingers, as aforesaid, he draws the under half of the mould towards the ball of his thumb, and thrusts by the ball of his thumb the upper part towards his fingers, that both the registers of the mould may press against both sides of the matrix, and his thumb and fingers press both halves of the mould close together.

Then he takes the handle of his ladle in his right hand, and with the ball of it gives a drizzle, two or three, outwards upon the surface of the melted metal, to draw or clear it from the blow or dull that may come upon it; then takes up the ladle full of metal, and having his mould as aforesaid, in his left hand, he a little twists the left side of his body from the furnace, and brings the great of his ladle (full of metal) to the mouth of the mould, and twists the upper part of his right hand towards him to turn the metal into it, while at the same moment of time he joss the mould with his left hand forwards, to receive the metal with a strong strike (as it is called); not only into the bodies of the mould, but while the metal is yet hot turning, (swift and strongly, into the very face of the matrix, to receive its perfect form there, as well as in the flanks.

Then he takes the upper half of the mould off the under half, by placing his right hand thumb on the end of the wood next his left hand thumb, and his two middle fingers at the other end of the wood; and finding the letter and break it in the under half of the mould (as most commonly by reason of its weight it does) he throws it to the left, back and all, upon a sheet of waste paper laid for that purpose on the bench, just a little beyond his left hand, and is then ready to cast another letter as before; and also, the whole number that is to be cast with that matrix.

A workman will ordinarily cast about three thousand of these letters in a day.

When the cinders in the furnace have got a sufficient number of types upon the cibles, a set of boys come, and nimble break away the jets from them; the jets are thrown into the pots, and the types are carried away in junks to other boys, who put them neatly under their fire, and defended by leather, upon smooth flat stones, in order to polish their lower sides. This is a very dextrous operation; and is a remarkable instance of what may be effected by the power of hand and some practices for it. In boys, in turning on the other side of the type, do it so quickly by a mere touch of the fingers of the left hand, as not to require the least perceptible assistance in the motion of the right hand upon the flanks. The types, thus nicely smoothed and finished on the broad sides, are next carried to another set of boys, who sit at a square table, two on each side, and there are ranged up on long rollers, or sticks, fixed with a small projection, to hinder them from sliding off backwards. When

these sticks are so filed, they are placed, two and two, upon a set of wooden pins fixed into the wall, near the drier, sometimes to the amount of a hundred, in order to undergo the finishing operations. This workman, who is always the most expert and skilful in all the different branches carried on at the foundry, begins by taking one of these sticks, and, with a peculiar address, fixes the whole column of types off upon the dressing stick; this is made of well seasoned mahogany, and furnished with two end pieces of fir, a little lower than the body of the types, one of which is moveable, fit to approach the other by means of a long screw pin inserted in the end of the sticks. The types are put into this stick with their faces next to the back or proclition and after they are adjusted to one another so as to stand even; they are then bound up, by passing home the moveable end piece. It is here where the great and regular accuracy of the moulds comes to be perceived; for in this case the whole column is bound up, lies flat and even upon the stick, the two extreme types being quite parallel, and the whole has the appearance of one solid continuous plate of metal. The next necessary in the exact parallelism of the individual type, which multiplied by many times, would render it impossible to bind them up in this manner, by dipping them to life or spring from the stick by the smallest pressure from the finger. Now, when lying so conveniently with the narrow edges uppermost, which cannot possibly be smoothed in the manner before mentioned by the stones, the workman does this more effectually by scraping the surface of the column with a thick-edged bar sharp razor, which at every stroke brings on a very fine smooth skin, like to polished silver; and thus he proceeds till in about half a minute he comes to the farther end of the stick. The other edges of the types are next turned upwards, and polished in the same manner. It is whilst the types thus lie in the dressing stick that the operation of braining or barring is performed, which is effected by turning a plane, faced with steel, along the shoulder of the body next to the face, which takes more or less off the corner, as occasion may require. Whilst in the dressing stick they are also ground, which is a very material operation. In order to understand this, it must be remembered, that when the type first breaks off from the jets, some superfluous metal always remains, which would make them lie very unequally against the paper whilst under the printing press, and eventually mar the impression. That all these inequalities may, therefore, be taken away, and that the bearing of every type may be regulated by the shoulders in part to turn all alike from the mould, the workman or drier proceeds in the following manner. The types being screwed up in the stick, as before mentioned, with the jet end outwardmost, and projecting beyond the wood about one eighth of an inch, the stick is put into an open press, so as to prevent the jet-end uppermost, and then every thing is made tight by driving a long wedge, which bears upon a slip of wood, which lies close to the types the whole length; then a plough or plane is applied, which is so constructed as to embrace the projecting part of the types, between its long sides, which are made of polished iron. When the plane is thus applied, the steel cutter bearing upon that part between the shoulders of the types, where the inequalities lie, the drier dextrously guides it along, and by this means strips off every irregular part that comes in the way, and to make an uniform groove the whole length, and leaves the two shoulders standing; by which means every type becomes precisely like to another, as to the height against paper. The types being now finished, the stick is taken out of the press and the whole column replaced upon the other stick; and after the whole are so dressed he proceeds to pick out the last letters, previous to putting them up into pages and papers. In doing this he takes the stick into his left hand, and turning the faces near to the light, he examines them carefully, and whenever an imperfect or damaged letter occurs, he nimble plucks it out with a sharp bodkin, which he holds in the right hand for that purpose. Those letters which, from their form, project over the body of the type, and which cannot on this account be rubbed on the stones, are scraped on the broad sides with a knife or file, and some of the most next the face pared away with a penknife, in order to allow the type to come close to any other. This operation is called kerning.

The excellence of printing types consists not only in the due performance of all the operations above described, but also in the hardness of the metal, form, and fine proportion of the character, and in the exact bearing and ranging of the letters in relation to one another.

FOUNDLING hospital. See *Foundling Hospital*.

FOUNT, or FONT, among *Printers*, &c. a set, or quantity, of CHARACTERS, or LETTERS, of each kind, call by a letter-founder, and sorted.

We say, a founder has cast a *font* of pica, of english, of pearl, &c. meaning that he has cast a set of characters of these kinds.

A complete *font* does not only include the running letter, but also majuscules, or large and small capitals, single letters, double letters, points, commas, lines, borders, head-pieces, tail-pieces, and numeral characters.

Fonts are large or small, according to the demand of the printer, who orders them by the hundred weight, or by sheets. When the printer orders a *font* of five hundred, he means that the *font* shall weigh five hundred pounds. When he demands a *font* of ten sheets, it is understood, that with that *font* he shall be able to compose ten sheets, or twenty forms, without being obliged to distribute. The founder takes his measure accordingly; he reckons a hundred and twenty pounds for a sheet, including the quadrats, &c. or sixty pounds for a form, which is half a sheet: not that the sheet always weighs a hundred and twenty pounds, or the form sixty pounds; on the contrary, it varies according to the size of the form; besides, it is always supposed that there are letters left in the cases.

The letter-founders have a kind of list, or *tanier*, whereby they regulate their *font*: the occasion thereof is, that some letters being in much more use, and oftener repeated, than others, their cells, or cases, should be better filled and flooded, than those of the letters which do not return so frequently.

Thus the *a*, and *i*, for instance, are always in greater quantity than the *k*, or *z*.

This difference will be best perceived from a proportional comparison of those letters with themselves, or some others. Suppose a *font* of a hundred thousand characters, which is a common *font*; here the *a* should have five thousand; the *e*, three thousand; the *i*, eleven thousand; the *o*, six thousand; the *m*, three thousand; the *n*, only thirty; and the *x*, *y*, and *z*, not many more. But this is only to be understood of the letters of the lower case: those of the upper having other proportions, which it would be, here, too long to insist on.

FOUNTAIN, Fons, in *Philosophy*, a spring, or source, of water, rising out of the ground.

For the phenomena, theory, origin, &c. of springs, or *fountains*, see *SPRING*.

Among the ancients, the *fountains*, or sources of rivers, were held sacred, and even worshipped, as a kind of divinities.

Seneca observes as much, in his forty-sixth epistle; and Cicero, lib. iii. De Nat. Deor. cap. 20. mentions, that the Roman priests, and augurs, used, in their prayers and invocations, to call on the names of the Tyber, and other rivers, brooks, and springs, about Rome. And the seventh inscription, in p. 94. of Gruter, has *PONTI DIVINO ET GENIO VMINIS FONTIS*.

It was a point of religion, not to disturb, or make mouldy, these waters in walking or bathing: Tacitus gives an instance hereof in Nero, Annal. lib. xiv. cap. 22.

FOUNTAIN, or artificial FOUNTAIN, in Hydraulics, a machine or contrivance, whereby water is violently spouted, or dashed up, called also a *jet d'eau*. See *JET d'EAU*, *FLUID*, &c.

There are divers kinds of artificial *fountains*; some founded on the spring, or elasticity of the air; and others, on the pressure, or weight, of the water, &c.

The structure of each of these being pretty curious, and affording a good illustration of the doctrine of hydraulics, and pneumatics, shall be here explained.

The theory of *fountains* may be collected from the articles *AIR*, *FLUID*, &c. and other particulars relating to their natures, and pipes of conduct, &c. may be found under *JET d'EAU*, and *MANSION OF WATER*.

FOUNTAIN. Construction of an artificial FOUNTAIN, playing by the spring, or elasticity of the air. A vessel, proper for a reservoir, as *AB*, Tab. II. *Hydraulica*, fig. 24 is provided, of metal, glass, or the like, ending in a small neck *a*, at the top; through this neck a tube is put, *d*, traversing the middle of the vessel, till its lower orifice *d*, nearly, but not absolutely, reach the bottom of the vessel; the vessel being first half filled with water. The neck is so contrived, as that a syringe, or condensing pipe, may be screwed upon the tube; by means whereof a large quantity of air may be introduced through the tube into the water, out of which it will disengage itself, and emerge into the vacant part of the vessel, and lie over the surface of the water *CD*.

Now, the water here contained being thus pressed by the air; which is, e. gr. twice as dense as the external air; and the elastic force of air being equal to its gravitating

force; the effect will be the same, as if the weight of the column of air over the surface of the water were double that of the column pressing in the tube: so that the water must, of necessity, spout up, through the tube, when the syringe is removed, with a force equal to the excess of pressure of the included, above that of the external air.

FOUNTAIN. Construction of an artificial FOUNTAIN, playing by the pressure of the water. Having the convenience of a fund, or reservoir of water, in a place considerably higher than that where the *fountain* is to be (whether that fund hath been placed there by nature, or whether it hath been raised for the purpose, by a proper engine, as a pump, siphon, spiral screw, or the like): from the reservoir lay vertical tubes, for the water to descend through; and, to these vertical tubes, fit other horizontal ones, under ground, to carry the water to the place, where the *fountain* is to play. Lastly, from these horizontal tubes, erect other vertical ones, by way of adjustments, jets, or spouts, their altitude being much less than that of the tubes whereby the water was carried to the horizontal ones.

Then will the water, by the pressure of the superincumbent column, be spouted up at these jets; and that to the height, or level, of the water in the reservoir; and this will be the case, howsoever any of the tubes be bent or incurved. The demonstration hereof, see under *FLUIDS*.

Thus may water be spouted to any given height at pleasure; and the tubes may be so proportioned as to yield any given quantity of water, in a given time; or several tubes, of the same *fountain*, may be made to yield water in any given ratio; or, lastly, different tubes may project the water to different altitudes. Rules for all which, the reader will find among the laws of *FLUIDS* and *JETS d'EAU*.

These aerial or aquatic *fountains* may be applied in various manners, so as to exhibit various appearances; and from these alone, arises the greatest part of our artificial water-works. An instance, or two, will not be disagreeable.

FOUNTAIN spouting the water in various directions. Suppose the vertical tube, or spout, in which the water rises, to be *AB* (Tab. II. *Hydraulica*, fig. 25.) into this fit several other tubes; some horizontal, others oblique; some inclining, others reclining, as *OP*, *MN*, *FL*, &c.

Then, as all water retains the direction of the aperture through which it is spouted, that issuing through *A* will rise perpendicularly; and that through *L*, *H*, *N*, *P*, *E*, will describe arches of different magnitudes, and tending different ways.

Or thus: suppose the vertical tube *AB*, fig. 26. through which the water rises, to be stopp'd at the top, as in *A*; and, instead of pipes, or jets, let it be only perforated with little holes all round, or only round half its surface: then will the water spin forth, in all directions, through the little apertures, and to a distance proportional to the height of the fall of the water.

And hence, if the tube *AB* be supposed the height of a man, and be furnished with an epistomium, or cock, at *C*, upon opening the cock, the spectators will be covered unexpectedly with a shower.

It may be here observed, that the diameters of the apertures by which the water is emitted, must be considerably less than those of the tubes in which the water is brought, lest the resistance of the air, and other impediments, specified under *FLUID* and *JET d'EAU*, break the force of the water.

FOUNTAIN playing by the danger of the bubble. Suppose *AB*, Tab. II. fig. 27. a glass, or metal-line sphere, wherein is fitted a tube *CD*, having a little orifice in *C*, and reaching almost to *D*, the bottom of the sphere. If, now, the air be sucked out of the tube *CD*, and the orifice *C* be immediately immersed under cold water, the water will ascend through the tube into the sphere.

Thus proceeding, by repeated extractions, till the vessel be above half full of water, and then applying the mouth to *C*, and blowing air into the tube, upon removing the mouth the water will spout forth.

Or, if the sphere be put in hot water, the air, being thereby rarified, will make the water spout as before. This kind of *fountain* is called *Pila Heronis*, or *Hero's ball*, from the name of its inventor.

FOUNTAIN, the stream whereof raises and plays a brass ball. Provide a hollow brass ball *A*, Tab. III. *Hydraulica*, fig. 28, made of a thin plate, that its weight may not be too great for the force of the water. Let the tube *BC*, through which the water rises, be exactly perpendicular to the horizon.

Then the ball, being laid in the bottom of the cup, or basin, *B*, will be taken up in the stream, and sustained at a considerable height, as *A*, alternately vibrating, or playing up and down.

Hence, as the figure of the ball contributes nothing to its reciprocal rise and fall, any other body, not too heavy, may be substituted in lieu thereof: e. g. a bird, with its wings stretched forth.

But note, that, as it is necessary the ball, when on the descent, should keep the same precise perpendicular wherein it rose (since, otherwise, it would miss the stream, and fall downright), such a fountain can only be played in a place free from wind.

FOUNTAIN which spouts water in form of a shower. To the tube wherein the water is to rise, fit a spherical, or lenticular head, AB, fig. 29. made of a plate of metal, and perforated at the top with a great number of little holes.

The water rising with vehemence towards AB, will be there divided into innumerable little threads, and afterwards broke, and dispersed into the finest drops.

FOUNTAIN which spreads the water in form of a tablecloth. To the tube AB, fig. 30. solder two spherical segments, C and D, almost touching each other, with a screw E, to contract or amplify the interstice or chink, at pleasure.

Others chuse to make a smooth, even cleft, in a spherical or lenticular head, fitted upon the tube.

The water spouting through this chink or cleft will expand itself in manner of a cloth.

FOUNTAIN, wherein the water spouts out of the figure of man, and other animals. Since water may be conveyed, by tubes in any situation, and always retains the direction of the aperture, all have required us, to invent close tubes within the figures of men, or other animals, having their orifices in those parts, whence the water is intended to spout forth.

From the principles hitherto laid down, it will be very easy to deduce whatever relates to the furniture of fountains, and the various forms water may be put into by their means; all depending on the magnitude, figure, and direction, of the apertures, or apertures.

FOUNTAIN, which when it has done spouting, may be turned like an hour-glass. Provide two vessels A and B, fig. 31. to be so much the bigger, as the fountain is to stay the longer; and placed at so much the greater distance from each other, as the water is desired to spout the higher. Let CDE be a crooked tube, furnished with a jet at F; and GHI another bent tube, furnished with a jet at J; KL and GF are to be other lesser tubes, open at both ends, and reaching near to the bottom of the vessels B and A, to which the tubes GH and CD are likewise to reach.

If, now, the vessel A be filled with water, it will descend through the tube CD, and will spout up through the jet E, by the pressure of the column of water CD. But unless the pipe GF was open at G, to let the air run up to F, and press at the top of the surface of the water in the cavity A, the water could not run down and spout at E. After its fall again, it will sink through the little tube KL, into the vessel B, and expel the air through the tube GI. At length, when all the water is emptied out of the vessel A, by turning the machine upside down, the vessel B will be the reservoir, and make the water spout up through the jet I, the pipe KL supplying B with air, to let the water descend in the direction GHI.

Hence, if the vessels A and B contain just as much water as will be spouted up in an hour's time, we shall have a spouting clepsydra, or water-clock; which may be graduated, or divided, into quarters, minutes, &c. as shown under CLEPSYDRA.

FOUNTAIN of command. This depends on the same principles with those of the former: CAE, fig. 32. is a vessel of water secured against the entrance of the air, except through the pipe GF, when the cock G, by which it was filled, is shut. There is another pipe EH, H B, which goes from the bottom of the water to the jet B in the basin DB, but this is stopped by the cock H. At the lowest part of the basin DB, there is a small hole at I to let the water of the basin DB run into the basin GH, under it; there is also a small triangular hole, or notch, in the bottom of the pipe FG, at G. Turn the cock H, and the fountain will play for some time, then stop, then play again alternately for several times together. When these times of playing and stopping are known before-hand, you may command the fountain to play or stop, whence its name. The cause of this phenomenon is as follows: the water coming down the pipe EDH B, would not come out at B, if the air S a, above the water, was not supplied as it descended; now it is supplied by the pipe GF, which takes in at the notch G, and delivers it out at F; but after some time the water, which has spouted out at B, falling down into the basin DB, rises high enough to come above the notch G, which stops the passage of the air so that the air S a,

above the water in the vessel CAE, wanting a supply, cannot sufficiently press, and the fountain ceases playing. But when the water of DB has run down into the lower basin HG, through the hole I, till it falls below the top of the notch G, the air runs up into the upper receptacle, and supplies that at S a, and the fountain plays again. This is seen a little before-hand, by a thin of water on the notch G, before the air finds a passage, and then you may command the fountain to play. It is evident, that the hole I must be less than the hole of the jet, or else all the water would run out into the lower basin, without rising high enough to stop the notch G.

FOUNTAIN that begins to play upon the lighting of candles, and ceases as they go out. Provide two cylindrical vessels, AB and CD, fig. 33. rounded then by tubes, open at both ends, KL, BE, &c. so that the air may descend out of the higher into the lower; to the tubes solder candlesticks, H, &c. and to the hollow cover of the lower vessel, CE, fit a little tube, or jet, FG, furnished with a cock G, and reaching almost to the bottom of the vessel. In G let there be an aperture, furnished with a screw, whereby water may be poured into CD.

Then, upon lighting the candles H, &c. the air in the contiguous tubes becoming rarefied thereby, the water will begin to spout through G F.

By the same contrivance may a statue be made to shed tears upon the presence of the sun, or on the lighting of a candle, &c. all here required being only to lay tubes from the cavity wherein the air is rarefied, to some other cavities placed near the eyes, full of water.

A FOUNTAIN may be made by the rarefaction of the air in the following manner: let AB and CD, fig. 34. be two pipes fixed to a table head C, made to screw into a glass vessel E, which, having a hole in its top, is inverted, till the pipes are screwed on; then covering it suddenly, so as to put A, the lower end of the floating pipe A into a jar of water A, and the lower end of the descending pipe CD, into a receiving vessel D, the water will spout up from the jar A into the tall glass vessel E, from which it will go down at the mouth C, through CD, into the vessel D, till the water is wholly emptied out of A, making a fountain in B, into D. The reason of the play of the fountain is this: the pipe CD, being two foot nine inches long, lets down a column of water, which rarefies the air in the vessel E, where it presses against the water spouting at B with the force by which the water is pushed up at the hole A, by the pressure of the common air on the water in the vessel A; so that the water spouts up into E, when the air is rarefied, & with the difference of the pressure of the atmosphere, and the forementioned rarefied air, i. e. of 33 to 24. This would raise the water two foot nine inches; but the length of the pipe A, nine inches being deducted, the jet will only rise two foot. This, says Deming, may be called a syphon fountain, where A B is the driving leg, and CD the sucking leg.

FOUNTAIN of HERR of Alexandria, so called, because it was contrived by him. In the first fountain already described, the air is compressed by a syringe, in this, see fig. 35. the air, being only compressed by the concealed fall of water, makes a jet, which, after some continuance, is considered by the ignorant as a perpetual motion; because they imagine that the same water which fell from the jet rises again. The boxes CE and D Y X, being close, we see only the basin ABW, with a hole at W, into which the water spouting at B falls; but that water does not come up again, for it runs down through the pipe WX into the box D Y X, from whence it dives out the air, through the ascending pipe YZ, into the cavity of the box CE, where, pressing upon the water, that is in it, it forces it out through the spouting pipe OB, as long as there is any water in CE; so that this whole play is only whilst the water contained in CE, having spouted out, falls down through the pipe WX into the cavity D Y X. The force of the jet is proportional to the height of the pipe WX, or of the boxes CE and D Y above one another: the height of the water measured from the basin ABW to the surface of the water in the lower box D Y X, is always equal to the height measured from the top of the jet to the surface of the water in the middle cavity at CE. Now, since, the surface CE is always falling, and the water in D Y always rising, the height of the jet must continually decrease, till it is stopped by the height of the depth of the cavity CE, which is emptying, added to the depth of the cavity D Y, which is always filling; and when the jet is fallen to low, it immediately ceases. To prepare this fountain for playing, which should be done unobserved, pour in water at W, till the cavity D Y X is filled; then invert the fountain, and the water will run from the cavity D Y X into the cavity CE, which may be known to be full, when the water

runs out at B held down. Set the fountain up again, and in order to make it play pour in about a pint of water into the basin ABW; and, as soon as it has filled the pipe WX, it will begin to play, and continue as long as there is any water in CE. You may then pour back the water left in the basin ABW, into any vessel, and invert the fountain, which being set upright again, will be made to play, by putting back the water poured out into ABW; and so on as often as you please.

The FOUNTAIN, fig. 36, is of the same kind; but, having double the number of pipes and concealed cavities, it plays as high again. In order to understand its structure, see fig. 37. The basin is A, the four cavities are B, C, D, and E, from which the water, through the pipe F, spouts up to double the height of the fountain; the air at E, which drives it, being doubly condensed. The water going down the pipe I (i. e. three feet long), condenses the air that goes up into the cavity C through the pipe 2, so as to make it stronger than the common air; then the water, which falling in the pipe 3 from C to D, is capable, by the height of its fall, of condensing the air at E, so as to make it stronger, being pushed at C by air already condensed into 2. In fact, causes the air at E to be condensed twice as much; that is, to be 4 stronger than common air; and, therefore, it will make the water at G spout out with twice the force, and rise twice as high as it would do, if the fountain had been of the same structure as the former. In playing this fountain, turn it upside down, and taking out the plugs a, b, fill the two cavities C and E, and having shut the holes again, set the fountain upright, and pour some water into the basin A, and the jet will play out at G; but the fountain will begin to play too soon; and, therefore, the best way is to have a cock in the pipe 3, which, being open, whilst the cavities C and E are filled, and shut again, before the fountain is set up, will keep the water thrown into the basin from going down the pipe 1, and that of the cavity C from going down the pipe 3, by which means the fountain will not play before its time, which will be as soon as the cock is opened.

FOUNTAIN, *dup. of Delaguerre*, is contrived to play by the spring of the air, increased by the heat of the sun, and serves also for a dial at the same time. GNS, fig. 38, is a hollow globe of thin copper, eighteen inches in diameter, supported by a small inverted basin, resting on a frame ABC, with four legs, between which there is a large basin of two feet diameter. In the leg C there is a concealed pipe, proceeding from G, the bottom of the inside of the globe, along IV, and joining an upright pipe U, for making a jet at L. The short pipe I, going to the bottom of the basin, has a valve at U under the horizontal part IV, and another valve at V above it, and under the cock, &c. At the north pole N, there is a screw for opening a hole, through which the globe is supplied with water. When the globe is half filled, let the machine be set in a garden, and, as the sun heats the copper and rarifies the included air, the air will press upon the water, which, descending through the pipe GCHV, will lift up the valve V, and shut the valve U, and the cock being open, spout out at L, and continue to do so for a long time, if the sun shines, and the airage be small. At night, as the air condenses again by the cold, the outward air, pressing into the aperture L, will shut the valve V, but by its pressure on the basin D & H, push up the water, which has been played in the day-time, through the valve U, and the pipe a H G into the globe, so as to fill it up again to the same height which it had at first, and the next fine-draw will cause the fountain to play again, &c. The use of the cock is to keep the fountain from playing till you think proper: a small jet will play six or eight hours. If the globe be set for the latitude of the place, and redlined before it be fixed, with the hour-lines or meridians drawn upon it, the hours marked, and the countries painted upon it, as in the common globe, it will be a good dial; the fin thing upon the same places in this globe, as it does upon the earth itself. Delaguerre, *Exper. Phil. vol. II. sect. 9. p. 205.*

FOUNTAIN, with regard to *Architecture*, is an assemblage of masonry, sculpture, &c. either for the decoration or convenience of a city, garden, or the like.

Fountains acquire various denominations, according to their form and situation: as,

FOUNTAIN, *arched*, that whole basin and jet are placed perpendicularly under the arch. Such are the fountains of the Colonnade, and the triumphal water-arch at Versailles.

FOUNTAIN, *basin*, is that with only a simple basin, of any figure whatever; in the middle whereof is a jet, or spout, or perhaps a statue, or even a group of figures. Such was formerly the fountain in the court of Buckingham-house.

FOUNTAIN, *covered*, a kind of pavilion, built of stone, either insulate, and square, or round, or multilateral, or

backed; and that either with a projection, or indented, including a recess, and spouting, or darning forth the water thereof through one or more cocks, in the middle of a square, square, garden, court, or the like. Such was that in Lincoln's-in-square, London.

FOUNTAIN, *cap*, is that which, beside a basin, has likewise a cup of one single piece of brass, or marble, supported on a shaft or pedestal, and receiving a jet, or spout, rising out of the middle thereof.

As the fountain in the court of the Vatican the cup whereof is of granite, and antique, being brought from the baths of Trajan at Rome.

FOUNTAIN, *marble*, that composed of aquatic figures, or sea divinities, rivers, tritons, rivers, dolphins, and other fishes, and shells. Such is the fountain of the palace of Palatrina at Rome, where a shell, supported by four dolphins, serves as a cup, and supports a triton, that spouts water out of his conchus marina.

FOUNTAIN, *metal*, is that made in the form of a vessel. Such is that of the place D'Espagne, at Paris, representing a bark; that at Montecassino, representing a galley; or that before the vineyard Maistre, at Rome, resembling a boat.

FOUNTAIN, *open*, is any spouting fountain with a basin, cup, or other ornaments, all open; such as are met with frequently in our gardens, and in the vineyards at Rome.

FOUNTAIN, *pyramidal*, that formed of several basins, or cups, ranged in stories over each other, and diminishing all the way, being supported by a hollow stem, or shaft. As the fountain of Monte-Dione, one at Versailles.

Or else supported by fountains, fishes, or conchoids the water whereof, in its fall, makes nests in divers fountains, and represents a kind of viney pyramid. As that at the head of the cascade at Versailles.

FOUNTAIN, *rock*, is that formed, or encircled, with rock-work, shell-work, peristyles, &c.

FOUNTAIN, *statue*, is a kind of statue fountain, in the manner of a statue, adorned with termini, musaerons, fawns, sylfens, bacchantes, and other fabulous figures, serving for ornaments, as well as jets d'eau.

FOUNTAIN, *spring*, or jet d'eau, is any fountain, whose water is directed forth impetuously through one or more jets, or apertures, and issues in form of rains, nets, falls, or the like. See *Jet d'Eau*.

FOUNTAIN, *stream*, a kind of plain spout, or stream of water, issuing out of a house, or hole in a wall, without any decoration. Such is the fountain of Trevi at Rome.

FOUNTAIN, *statuary*, that which, being opened and inflated, is even-backed, is adorned with one or more statues, by way of finishing, or crowning. As the fountain of Latona, at Versailles; and that at the Shephard at Caprasia.

There are, also, statues which spout forth water at some of their parts; or at sea-shells, valves, arms, and other attributes of the sea.

FOUNTAIN, *symbolical*, that where the principal ornaments are the attributes, arms, or cognizances, of the person who erected it. Such are the fountain of St. Peter in Montorio, resembling a castle flanked with towers, and domes, representing the arms of Coligny; and some other fountains at Rome among which are the beardless, and the dove, the breast of the family of pope Innocent X.

FOUNTAIN, *pen*, is a sort of pen contrived to contain a great quantity of ink, and let it flow, by gentle degrees, so as to supply the scribe a long time without a necessity of making fresh ink.

The fountain-pen, represented *Tale. Affection. fig. 15.* consists of divers pieces, F, G, H, of body silver, &c. whereof the middle piece F makes the pen, which is screwed into the middle of a little pipe which, again, is soldered to another pipe of the same body silver, as the lid G; in which lid is soldered a male screw, for forcing on the covers a, also, for stopping a little hole at the place, and hindering the ink from passing through it; at the other end of the piece F is a little pipe, on the outside whereof the top cover H may be screwed. In the cover there goes a perforation, to be screwed into the lid mentioned pipe, in order to stop the end of the pipe into which the ink is to be poured by a funnel.

To use the pen, the cover G must be taken off, and the pen a little shaken, to make the ink run more freely.

FOUR-CORNERS, in the *Mange*, or to work upon the four-corners, is to divide in imagination the volt or round into four quarters; so that, upon each of these quarters, the horse makes a round or two at trot or gallop; and when he has done so much upon each quarter, he has made the four-corners.

FOUR, *col de four*. See *Chari*.

FOURCHEE, or FOURCHY, in *Horology*. A crows foot is that forked at the ends.

Upon rather requires it, as anchored, the extremities turning

turning in a circular manner to sharp points; whereas the true cross *fourche*, i. e. forked, has its forks composed of straight lines, and blunt ends. See *Tab. Herald. fig. 33*. **FOUCHIER**, an ancient law term, signifying a putting off, prolonging, or delaying, an action.

As by hammering we draw out our speech, not delivering that we have to say in ordinary times, so by *fourche* we prolong a suit, that might be ended in a shorter space. In Stat. Westm. 1. cap. 42. we have these words: "Co-tenants and joint-tenants shall be no more *fourche*, but only shall have one *fourche*," &c. And anno 6 Edw. 1. cap. 10. it is used in the same sense: "The defendants shall be put to answer without *fourche*," &c. In the Latin it is called *forca*, and is used where a man and his wife do coiten severally. *Curat vir & uxor implacitum, quod semper in iissem aliter aliter comparat, quando forcat possit; & cum aliter non possit, curat utrumque iissem in suis iis: aliter autem eorum iudicium non iudicium de male iissem possit.* Hengham mag. cap. 9.

FOURCHETTE. *For de FOURCHETTE*. See *FOR*. **FOURMILLIER**, in Zoology, the name given by Buffon to the *myriophaga didactyla* of Linnaeus, or the little ant-eater; or lesser yellowish tomard; or the white American cat. This animal has a curious nose bending a little downwards, ears that are small and hid in the fur, two hooked claws on the fore-feet, and four on the hind-feet; the head, body, limbs, and upper part and sides of the tail, are covered with long, soft, silky hair, or rather wool, of a yellowish brown colour; the tail is thick at the base, and tapers to a point. This species inhabits Guiana, and climbs trees in search of ants, which build their nests in the branches. *Tab. II. Quadrup. N° 11*. See *ANT-eater*.

FOURTH, in Music, one of the harmonic intervals, or concords.

The *fourth* is the fourth in order of the concords. It consists in the mixture of two sounds, which are in the ratio of 4 to 3, i. e. of sounds produced by chords, whose length are to each other as 4 to 3. It is called *fourth*, because containing four terms, or sounds, between its extremes, and three degrees; or, as being the *fourth* in the order of the natural scale, from the fundamental.

The ancients call the *fourth* *DIATESSARON*, and speak of it as the first and principal of all concords; and yet the moderns find it one of the most imperfect. It is too very barren and jejune, that it affords nothing good, either by multiplication or division.

Some modern musicians have doubted whether the *fourth* should be received among the number of concords, or not. The ancients expressly admitted it as such, and Andreas Papias wrote a treatise against those moderns who reject it. *Meis. Harm. lib. iv. prop. 8*. Wallis, *Append. Polém. Harm. p. 182*.

FOURTH, diminished, in Music. See *DIMINISHED fourth*. The redundant *fourth* is a discord composed of the ratios of 27 to 20, and of 4 to 5.

Artes of the FOURTH part. See *ARCS*.

FOURTH part. See *RATE*.

FOUTGELD, or FOOTGELD. See *FOOTGELD*.

FOWL, in a general sense, is of equal import with *BIRD*. *Fowl*, is, in a more peculiar manner, understood of poultry, or the larger sort of birds, both domestic and wild, either bred up, or hunted for the table.

Such as turkeys, geese, cocks, hens, and ducks both wild and tame, pheasants, partridges, pigeons, snipes, &c.

Our common poultry came originally from Persia and India. Aristophanes calls the cock the Persian bird, and that it was known in that country before Darius and Megabyzus; and these birds are now found wild in the life of Tunis, and other islands in the Indian ocean; in this state their plumage is black and yellow; and their combs and wattles purple and yellow. They have been naturalized in this country before the arrival of the Romans; for Ovid informs us, that they were one of the forbidden foods of the old Britons. They were probably imported by the Phoenicians, who traded to Britain about five hundred years before Christ. For all other domestic *fowls*, turkeys, geese, and ducks excepted, we seem to be indebted to our conquerors, the Romans. The wild *fowl* were our own from the earliest period.

Pennant. The belly of a living *fowl* being split up, the creature is thus applied to a part bit by a rattle-snake, to draw out some of the poison. It seems to have some effect this way. We find an instance in the Philosophical Transactions, where a *fowl* thus applied to a hand bit by that most venomous snake, immediately swelled, grew black, and sunk. N° 479. p. 144.

The *sea-fowls* which come on shore in immense numbers to roost, in the north islands of Scotland, set their watches

and sentinels at distant posts, to give them notice of any danger; on the least alarm from thence, the whole body rises, but without such notice they are not to be alarmed by almost any thing. The people of the country know this; and when they go out to take them, they employ all their art to take the sentinels without noise; this they sometimes succeed in, and when they do, they often afterwards catch three hundred of the others, or more, in one night. Phil. Trans. N° 333.

The laying of these sea birds is less certain as to time than might be imagined. They can occasionally defer it; and as they usually lay in a rainy season, if the rain does not come on at the usual time, they will defer it some weeks; and if the April moon goes far in May, that also has been observed to hinder them from laying ten or twelve days longer than ordinary. See *BIRD*.

FOWL, *hens*, are a necessary part of the flock of a country farm; and yield considerable service and profit, by their EGGS, MEAT, FEATHERS, &c. &c. They may be kept at a very easy expence near any highway-side; as being able to thrust for themselves, during the greater part of the year, by their feeding on insects, worms, snails, and almost any thing edible. The oldest hens are always the best for laying, and the youngest for laying; but too fast will be good for either, if kept too fast.

The best age to set a hen for *CHICKENS*, is, from two years old to five; and the most proper month to set them in, is February; though it may be done, to good purpose, at any time between that and Michaelmas. One cock will serve ten hens. A hen sets but twenty days whereas geese, ducks, and turkeys, 45 days.

Buckwheat, or French wheat, or hempseed, it is said, makes them lay faster than any other food; and the same buckwheat, either whole, or ground, and made into a pottage, fast them up; though the common food, for that purpose, is barley-meal, or pollard mixed up with hot water or milk. A goose will fence it on any but her own eggs; a hen will sit indifferently on all.

The lightest coloured geese are the best, and those that begin to lay the soonest; as they have a chance of hatching twice in one year. They begin to lay in the spring, and lay twelve or sixteen eggs. Geese eggs are begun to be fattened at a month old, and will be fat in a month more. Old geese are chiefly fattened at six months old, in or after the harvest. A wild goose, if red-footed and hairy, is old; but if white-footed, and not hairy, the is young.

When the eggs are set under a hen, or other *fowl*, it is advisable to mark the upper side thereof; and when the goes to feed, to note whether he minds to turn them upside down, or not; that if he neglect that office, it may be done for her.

FOWL, *water*, may be taken in great abundance by nets properly managed. The net for this purpose should be always made of the finest and strongest packthread that can be got. The meshes may be large, but the net should be lined on both sides with other smaller net, every mesh of which is to be about an inch and a half square each way, that as the *fowl* strike either through them or against them, the smaller may pass through the great meshes, and so frighten and entangle the *fowl*.

These nets are to be pitched for every evening flight of *fowl*, about an hour before sun-set, fixing them on each side of the river, about half a foot within the water, the lower side of the net being to plummet, that it may sink to far and no farther; place the upper side of the net handwise, floating against the water, but not touching it by near two fathoms; and let the stings, which support this upper side of the net, be fastened to wait yielding sticks set in the bank; these as the *fowl* strike, will give the net liberty to play, and to entangle them. Several of these nets should be placed at equal or different parts of the river, at about twelve-score fathom distance one from another; and if any *fowl* come that way, the sportman will have a share of them. It is a good method, when the nets are set, to go to places suitably distant from them with a gun, to fright them toward the places where the nets are; and wherever any of the *fowl* are hunted from, it may not be amiss to plant some net also there, to take them as they return. The nets are to be left thus placed all night, and in the morning the sportman is to go and see what is caught; he should visit the river first, and take up what are caught there, and, frightening the rest away to the other places where his nets are, he is next to visit them, and take what are there secured.

The Ceyloneese have great plenty of water-fowl in their islands, and have a very remarkable way of catching them, which is this: the fowler enters a lake or other water which has a good bottom, and is not very deep; he puts an earthen pot upon his head, in which there

are bored holes, through which he can see; he keeps himself so bent down in the water, that only the top of his head is above the surface; in this manner he enters the place where the wild-fowl are in cloisters, and they think it is only some floating block. He then takes some one by the legs, and gently draws it under water, and wrings its neck till he has killed it; then putting it into his bag, which is fastened about his middle, he takes hold of another in the same manner, and so on, till he has got as many as he can carry off, and then he goes back in the same manner in which he came, not disturbing the rest of the birds, who never miss their companions, but only suppose that they dive down for their diversion, when the fowler pulls them under. In places where this has been practised to long or so carefully that the birds are shy, the fowler uses a gun; but this he does in the following manner: he makes a fence of about five foot high, and three foot wide, which he carries in one hand straight between himself and his game, and in the other hand his gun. The birds are not alarmed at what appears only a bush; for this fence is always covered with branches of trees fresh cut down, and full of leaves, so that the sportsman behind advances as near as he pleases, and then putting the gun through some crevice of the fence, he fires. See *DUCK*; see also account of experiments on *water-shoots*, with regard to their faculty of respiration, under the article *DUCK*.

FOWL, wild, driving of. See *DRIVING*.

FOWLING, the act, or art, of catching birds with NETS, BIRDLINES, DECOYS, and other devices; as also of breeding up the fowls.

FOWLING is also used for the pursuing and taking of birds with hawks, falcons, and other birds of prey; more properly called *FALCONRY* and *HAUKING*.

FOWLING-piece, a portable fire-arm for the shooting of birds.

Of *fowling-pieces*, there are reputed the best, which have the longest barrel, viz. from 33 feet to 6, with a moderate bore; though, for different occasions, they should be of different sorts and sizes: but in all, it is essential the barrel be well polished, and smooth within, and the bore of an uniform bigness, from one end to another; which may be proved by thrusting in a piece of wood, cut exactly to the bore of the muzzle, down to the touch-hole; for it this goes down without flapping, you may conclude that the bore is good. The trigger-pan should be a little above the touch-hole, and ought to have a notch to let down a little powder, which will prevent the piece from recoiling. The locks should be accurately filed, and their springs be neither too strong nor too weak. The hammer ought to be well hardened, and pliable, so as to go down to the pan with a quick motion. In shooting, observe to do it with the wind, if possible, and rather side-ways, or behind the fowl, than fall in their faces. Observe also to chuse the most convenient shelter, as a hedge, bank, or tree. If you have not shelter enough, you must creep on your hands and knees, or use a stalking horse. Let your dogs be under good command. See *SETTING DOGS*, *WATER DOGS*, and *SPANIEL*.

FOX, *Vulpes*, in Zoology, an animal of the dog kind, much resembling the common dog in form, and of the size of the spaniel. It is chiefly distinguished by its long straight tail, with a white tip to it. See *CANIS* and *DOG*. It differs, however, from the common dog in the length, dense disposition, and softness of the hairs, especially those about its tail, which is bushy, much admired by the animal itself, and in cold weather wrapped round its nose; and in its smell, which is peculiarly rank and disagreeable. The smell of its urine is remarkably fetid; inasmuch that the animal covers it in the earth. It is said that the fox makes use of its urine as an expedient to force the cleanly badger from its habitation; however, it makes use of the badger's hole. Its usual colour is a reddish tawny, though it is sometimes found white, and sometimes black. Its manner of digging itself a hole in the earth, is also a custom wholly different from all the dog-kind; and it is far from the manners of that animal, being with difficulty made to live in society. Of all animals the fox has the most significant eye, by which it expresses every passion of love, fear, hatred, &c. The fox is a crafty, lively, thievish animal: it breeds only once in a year, unless some accident befalls its first litter, and brings four or five young, which, like puppies, are born blind.

The fox is a native of most northern countries, and there are three varieties of it, differing a little in form, but not in colour. They are distinguished in Wales by different names. The greyhound fox is the largest, tallest, and boldest, and will attack a grown sheep or wether; the mastiff fox is less, but more strongly built; the cur fox is the least, looks about hedges, out-houses, &c. and is the most pernicious to the feathered tribe. The first of these has a white tip to the tail; the last a black. The skin of this animal is furnished with a soft and warm fur,

Vol. II. N° 140.

which in many parts of Europe is used to make mitts and fine cloths.

A fox in the first year is called a cub; in the second, a fox, and afterward an old fox. It is a beast of chase, usually very prejudicial to the husbandman, by taking away and destroying his lambs, geese, and poultry. It will feed on flesh of any kind; and when urged by hunger eat carrion and insects; and, near the low-land, for want of other food, eat crows, thrushes, or field-larks. In France and Italy it does incredible damage in the vineyards, by eating the grapes, of which it is very fond. The fox is a great destroyer of rats, and field animals. It secures its booty by digging holes in several places; and if a whole flock of poultry should happen to be its prey, will bring them one by one, thrust them in with its nose, and conceal them by ramming the loose earth upon them, till the calls of hunger induce them to devour them. The common way to catch him is by gins, which being baited, and a trap made by drawing saw fish across his usual paths or haunts to the gin, it proves an indurment to lure him to the place of destruction. They are also taken with greyhounds, hounds, terriers, and nets: it is a commendable exercise to hunt the mischievous beast, the nature of which in many respects is like that of wolves. See *HUNTING*.

FOX, fish. See *ALOEPEX*.

FOX, *Striaris*. See *LACOPER*.

FOX, fish, vulgar *marinus*, in Ichthyology, the name given by authors to a large fish, called the *poofox* by us. In the Arabian Syden it is the *SOALUS*, with a tail longer than the body. It is said by many authors to have naturally the rank smell of the fox, and to be one of the worst-tasted fishes; but this does not appear to be true, on strict enquiry; for its smell seems very little different from that of other fishes, and its flesh is well-tasted; so that these things seem only to have been said, in order to strengthen the resemblance with the fox, a name which seems, upon the whole, to have been given it only from the length of its tail; and even that, though very long for a fish of this kind, has no resemblance with the tail of a fox. The length of this fish is about nine feet, sometimes twelve or thirteen, and its breadth, in the broadest part of the belly, fourteen inches. Its tail is nearly as long as the whole body, and is of the shape of a scythe, and is bent downwards. Near the origin of the tail, it has a single fin below, and the spine is more movable up and down in this part, than in any other; so that the tail is, by this means, easily elevated or depressed. It has two emarginations on the back, a large one near the middle, and a small one near the tail. It has three fins on each side; the pair near the head are large, and resemble the wings of a bird; the others are smaller. The fin is smooth, and without scales; and the fins and emarginations on the back are composed of a sort of ribs, held together by a tough and strong membrane. The tongue adheres inseparably to the lower jaw, and is composed of a great number of bones, articulated together by a fleshy substance of a fibrous texture, and covered with a membrane, in which there are several prominences, which, when viewed with the microscope, appears as pellucid as the finest crystal. Its throat and stomach are remarkably large, and authors say, that when in a fright it will swallow its young ones into its stomach, and afterwards cast them up again when the danger is over. Others, who speak largely of its cunning, say, that when it has swallowed a bait at a hook, it will take in the whole line, till it comes to a weak place, where it can bite it asunder. This is a tale very well calculated for the carrying on a resemblance with the fox in cunning; but it is very ill adapted to this fish, which has no teeth with which it can bite any thing asunder. The heart of this fish is remarkably small, nothing larger than a hen's egg; it is also much of the same shape, and has no pericardium; but the aorta for a little way is covered with a membrane analogous to a pericardium. The head seems a mere lump of flesh, being covered with mottles, of which some are four inches thick; and though the head is so large, the skull is not bigger than a man's fist; it is thick, and is divided within into three cavities, each of which contains a small quantity of a mucous matter mixed with blood; so that the fish seems forced to have any brain at all, what little matter of it there is being quite soft, and having very few windings. The eyes are as large as those of an ox, and are only demispheric in figure, being flat before, so that they appear of a very singular shape. Mem. pour Hist. Anim. p. 114.

The teeth are triangular, small, and placed in three rows; the back is an ash colour, and the belly white. The guts of this fish have a very peculiar structure. In the upper part of them, instead of the ordinary circulations of the guts of animals, the cavity is distinguished by many transverse separations, composed of the membranes of the intestine turned inwards; these separations

rations stand at about half an inch distance from one another, and turn helvally like a snail-shell. The consequence of this is, that the food is detained a long time in its passage, though the way it has to go be very short. This creature feeds both on other fish, and on sea-plants. *Ouvrage adopté de l'Acad. Par. vol. 1.*

This fish has been sometimes taken in our seas, and imagined to be the fish called the shrewfish, from its attacking and beating the grampus with its long tail, when it rises to the surface to breathe.

FOX, in Sea Language, signifies a sort of strand, formed by twining several ropes together, and used as a seizing, or to weave a mat or punch, &c.

FOX-GLOVE, *Digitalis*, in Botany, a genus of the *dipsacaceae angustifolia* class. Its characters are these: the flower is bell-shaped, of one petal, with a large open tube, whose brim is slightly divided into five parts; it has four stamens, which are inserted in the base of the petal, two being longer than the others; the germens surround the ovary in an oval capsule, having two cells inclosing many small angular seeds. Linnaeus enumerates six and Miller nine species, which are great ornaments to a garden. All these sorts should be sown in autumn; for if the seeds are sown in the spring, they commonly fail, or at least lie a whole year in the ground before they begin to vegetate. The plants, one species excepted, are biennial, and perish as soon as the seeds are ripe. Miller. The common *fox-glove*, or the purple *fox-glove*, with a rough leaf, grows wild in woods, and on heaths; flowers in June, and the seeds ripen in autumn. The leaves communicate a bitterish and mucous taste, both to watery and spiritous menstrua: and have been strongly recommended in epileptic disorders. It operates by stool and vomit, but with such violence, that it is now disused. Boerhaave judges it to be of a poisonous nature; Dr. Aitken, on the contrary, ranks it among those indigenous vegetables, which, though now disregarded, are medicines of great virtue, and scarcely inferior to any that the Indies afford. Externally, the leaves and flowers have been employed with great safety, and with success, in cataplasms and unguents for ill-conditioned ulcers. The *fox-glove digitalis* takes its name from this plant. *Lewis's Mat. Med.*

FOX-GLOVE. See **GRAM.**

FOYLING of Land, among Farmers, the FALLOWING it in summer and autumn.

FOULING, among Sportsmen, a term used for the footstep of a stag, on the grass or leaves.

FOYNA, in Zoology, a name given by many to the MARTIN or MARTIN, an animal of the weasel-kind, common with us.

FRACHES, in the Glass-Trade, are the flat iron pans into which the glass vessels already formed are put, when in the tower over the working furnace, and by means of which they are drawn out through the leers, that they may be taken gradually from the fire, and cool by degrees.

FRACTION, in Arithmetic and Algebra, a part or division of an unit, or integer; or, a number which stands to an unit in the relation of a part to its whole.

The word literally imports a broken number.

Fractions are usually divided into *decimal, sexagesimal, and vulgar.*

For *decimal, and sexagesimal fractions*, see **DECIMAL**, and **SEXAGESIMAL**.

FRACTIONS, Vulgar, called also simply, *fractions*, are always expressed by two numbers, the one wrote over the other, with a line between them.

The lower, called the *denominator of the fraction*, denotes the unit, or whole, that is divided into parts; and the upper, called the *numerator of the fraction*, expresses the parts given in the present case.

Thus, two-third parts of a line, or other thing, are wrote $\frac{2}{3}$; where the denominator 3 shews that the whole line is supposed to be divided into three equal parts; and the numerator 2 indicates or assigns two of such parts.

Again, twenty-nine sixtieths is wrote $\frac{29}{60}$; where the numerator 29 expresses 29 parts of an integer divided into 60; and the denominator 60 gives the denomination to these parts, which are called *sixtieths*.

The real design of adding the denominator is, to shew what aliquot part the broken number has in common with unity.

In all *fractions*, as the numerator is to the denominator, so is the *fraction* itself to the whole whereof it is a *fraction*.

Thus, supposing $\frac{1}{2}$ of a pound equal to 15s. it is evident, that $\frac{3}{4}$ is 15s. 20. Whence it follows, 1^o. That there may be infinite *fractions* of the same value, one with another; inasmuch as there may be infinite numbers found, which shall have the ratio of 3 to 4.

Fractions are either *proper, or improper.*

FRACTION, Proper, is that where the numerator is less

than the denominator; and, consequently the *fraction* less than the whole, or integer, as $\frac{1}{2}$.

FRACTION, Improper, is where the numerator is either equal to, or bigger than the denominator; and of course the *fraction* equal to, or greater than the whole, or integer, as $\frac{3}{2}$ or $\frac{5}{4}$, or $\frac{7}{3}$.

Fractions, again, are either *simple, or compound.*

FRACTIONS, Simple, are such, as consist of only one numerator, and one denominator, as $\frac{1}{2}$, or $\frac{3}{4}$, &c.

FRACTIONS, Compound, called also *fractions of fractions*, are such as consist of several numerators, and denominators; as $\frac{1}{2}$ of $\frac{3}{4}$, or $\frac{1}{3}$ of $\frac{2}{5}$, &c.

Of *fractions*, those are equal to each other, whose numerators have the same ratio to their denominators. — Those are greater, whose numerators have a greater ratio; and those less which have less; thus, $\frac{1}{2} > \frac{1}{3}$, $\frac{2}{3} > \frac{1}{4}$, &c. But $\frac{1}{2}$ is greater than $\frac{1}{3}$ and $\frac{1}{4}$ less than $\frac{2}{3}$. Hence if both the numerator, and denominator of a *fraction*, as $\frac{1}{2}$, be multiplied or divided by the same number, 2; the field in the former case, $\frac{2}{4}$, and the quotient in the latter $\frac{1}{4}$, will constitute *fractions* equal to the first *fraction* given.

The arithmetic of *fractions* consists in the *reduction, addition, subtraction, and multiplication* thereof.

REDUCTION, reduction of 1. To reduce a given whole number into a fraction of any given denominator. Multiply the given integer, by the given denominator, the product will be the numerator. Thus we shall find $3 = \frac{3}{1}$ and $4 = \frac{4}{1}$, &c.

If no denominator be given, the number is given as a *fraction*, by writing 1 underneath it, as a denominator. Thus $2 = \frac{2}{1}$.

2. To reduce a given fraction to a fraction equal to it, that shall have a given denominator. Multiply the numerator by the given denominator, and divide the product by the former denominator, and the quotient for over the given denominator is the *fraction* required. Let it be proposed to reduce $\frac{1}{2}$ to an equal *fraction* with the denominator 8; $8 \times \frac{1}{2} = 4 = \frac{4}{8}$.

3. To reduce a given fraction to its lowest terms; i. e. to find a *fraction*, equivalent to a given *fraction* ($\frac{12}{20}$), but expressed in less numbers: divide both the numerator 12, and denominator 20, by some one number, that will divide them both without any remainder, as here by 4. The quotients 3 and 5 make a new *fraction* $\frac{3}{5}$ equal to $\frac{12}{20}$.

And if the division be performed with the greatest number that will divide them both, the *fraction* is reduced to its lowest terms. See **COMMON MEASURE**.

If it happens that unity is the only common measure of the numerator and denominator; then is the *fraction* incapable of being reduced any lower; and numbers whose greatest common measure is unity, are said to be **PRIME** to each other.

4. To reduce two or more fractions to the same denomination; i. e. to find *fractions* equal to the given ones, and with the same denominator. Multiply each numerator, separately taken, into all the denominators but its own, and the products shall give the new numerators. Then multiply all the denominators into one another, and the product will be the common denominator. Thus, $\frac{1}{2}$ and $\frac{1}{3}$ are $\frac{3}{6}$ and $\frac{2}{6}$; and $\frac{1}{4}$ and $\frac{1}{5}$ are respectively $\frac{5}{20}$, $\frac{4}{20}$, and $\frac{1}{6}$.

5. To find the value of a fraction, in the known parts of its integer. Suppose, e. g. it were required to know what is $\frac{3}{4}$ of a pound; multiply the numerator 3 by 20, the number of known parts in a pound, and divide the product by the denominator 4; the quotient gives 15s. Then multiply the remainder 3 by 12, the number of known parts in the next inferior denomination; and dividing the product by 4, as before, the quotient is 3d. So that $\frac{3}{4}$ of a pound = 15s. 3d.

6. To reduce a mixed number, i. e. a number partly integral, and partly fractional, as $4\frac{1}{2}$, into an improper fraction of the same value. Multiply the integer, 4, by 2; the denominator of the *fraction*; and to the product 8 add the numerator; the sum 10 is over the former denominator, 2; constitutes the *fraction*.

7. To reduce an improper fraction into its equivalent mixed number. Suppose the given *fraction* $\frac{17}{4}$; divide the numerator by the denominator; the quotient is the integral part, and the remainder set over the denominator will be the fractional part. Thus, $\frac{17}{4} = 4\frac{1}{4}$.

8. To reduce a compound fraction into a simple one. Multiply all the numerators into each other for a new numerator; and all the denominators for a new denominator. Thus $\frac{1}{2}$ of $\frac{2}{3}$ of $\frac{3}{4}$ reduced will be $\frac{1}{4}$.

9. To reduce a vulgar fraction to a decimal of the same value. See **DECIMAL**.

FRACTIONS, addition of vulgar. 1. If the given *fractions* have different denominators, reduce them to the same. Then add the numerators together, and under the sum write

write the common denominator. Thus, e. gr. $\frac{3}{4} + \frac{1}{2} = \frac{3}{4} + \frac{2}{4} = \frac{5}{4}$.

2. If compound fractions are given to be added, they must first be reduced to simple ones; and if the fractions be of different denominations, as $\frac{1}{2}$ of a pound, and $\frac{1}{4}$ of a shilling, they must first be reduced to fractions of the same denomination of pounds.

3. To add mixed numbers. The integers are first to be added, then the fractional parts; and if the sum be a proper fraction, only annex it to the sum of the integers. If it be an improper fraction, reduce it to a mixed number, adding the integral parts thereof to the sum of the integers, and the fractional part after it. Thus, $5\frac{3}{4} + 4\frac{1}{2} = 10\frac{5}{4}$.

FRACTIONS, subtraction of. 1. If they have the same common denominator, subtract the lesser numerator from the greater, and let the remainder over the common denominator. Thus from $\frac{3}{4}$ take $\frac{1}{4}$, and there remains $\frac{2}{4} = \frac{1}{2}$.

2. If they have not a common denominator, they must be reduced to fractions of the same value, having a common denominator, and then, as in the first rule. Thus, $\frac{3}{4} - \frac{1}{2} = \frac{3}{4} - \frac{2}{4} = \frac{1}{4}$.

3. To subtract a whole number from a mixed number, or a mixed number from another. Reduce the whole, or mixed numbers to improper fractions, and then proceed as in the first and second rule.

FRACTIONS, multiplication of. 1. If the fractions proposed be both simple, multiply the numerators one by another for a new numerator, and the denominators for a new denominator. Thus $\frac{1}{2} \times \frac{3}{4}$ produces $\frac{3}{8}$.

2. If one of them be a mixed, or whole number, it must be reduced to an improper fraction; and then proceed as in the last rule. Thus $\frac{1}{2}$ into $5\frac{3}{4}$, gives $2\frac{3}{4}$, and $\frac{3}{4}$ into $5\frac{3}{4}$ is $4\frac{1}{4}$.

In multiplication of fractions, observe that the product is less in value, than either the multiplicand, or multiplier; because in all multiplications, as unity is to the multiplicand, so is the multiplier, to the product; or, as unity is to the other factor, so is the other factor, to the product. But unity is bigger than either factor, if the fractions be proper; and therefore either of them must be greater than the product.

Thus, in whole numbers, if 3 be multiplied by 8, it will be as 1:3::8:40; or 1:8::3:40. Wherefore in fractions, also, as 1: $\frac{1}{2}$:: $\frac{3}{4}$: $\frac{3}{8}$; or as 2:1:: $\frac{3}{4}$: $\frac{3}{2}$. But 1 is greater than either $\frac{1}{2}$, or $\frac{3}{4}$; wherefore either of them must be bigger than $\frac{3}{8}$.

FRACTIONS, division of. 1. If the fractions proposed be both simple, multiply the denominator of the divisor by the numerator of the dividend; the product is the numerator of the quotient: then multiply the numerator of the divisor by the denominator of the dividend; the product is the denominator of the quotient. Thus $\frac{3}{4} \div \frac{1}{2} = \frac{3 \times 2}{4 \times 1} = \frac{6}{4} = \frac{3}{2}$. Or, invert the divisor and proceed as in multiplication.

2. If either dividend, divisor, or both, be whole, or mixed numbers, reduce them to improper fractions; and if they be compound fractions, reduce them to simple ones, and proceed as in the last rule.

In division of fractions observe, that the quotient is always greater than the dividend; because in all divisions, as the divisor is to unity, so is the dividend to the quotient: as if 3 divide 12, it will be, as 3:1::12:4. Now 3 is greater than 1; wherefore 12 must be greater than 4: but in fractions, as $\frac{1}{2} : 1 :: \frac{3}{4} : \frac{3}{2}$; where, $\frac{1}{2}$ is less than 1; wherefore $\frac{3}{4}$ must also be less than $\frac{3}{2}$.

FRACTIONS in species, or algebraic quantities. 1. To reduce fractions in species to their last terms. The numerators and denominators are to be divided by the greatest common divisor, as in numbers.

Thus the fraction $\frac{a^2b}{bc}$ is reduced to a more simple one $\frac{a^2}{c}$ by dividing both a^2b and bc by c ; and $\frac{203}{667}$ is reduced to a more simple one $\frac{7}{203}$ by dividing both 667 by 203 and $\frac{203}{667}$ is reduced to $\frac{7}{23}$ by dividing by 203. And $\frac{6at-9abc}{9aa+3ac}$ becomes $\frac{2a-3bc}{3a+c}$ by dividing by 3a. And $\frac{a^2-ab+ab-b^2}{aa-ab}$ becomes $\frac{a+b}{a-b}$ by dividing by $a-b$. See COMMON MEASURE.

2. To reduce fractions in species to a common denominator. The terms of each are to be multiplied by the denominator of the other.

Thus, having $\frac{a}{b}$ and $\frac{c}{d}$; multiply the terms of one $\frac{a}{b}$ by d , and also the terms of the other $\frac{c}{d}$ by b , and they

will become $\frac{ad}{bd}$ and $\frac{bc}{bd}$ whereof the common denominator is bd . And thus a and $\frac{bc}{d}$, or $\frac{a}{1}$ and $\frac{bc}{d}$, become $\frac{ad}{d}$ and $\frac{bc}{d}$.

But where the denominators have a common divisor, it is sufficient to multiply them alternately by the quotients.

Thus the fractions $\frac{a^2}{bx}$ and $\frac{a^2}{bd}$ are reduced to these $\frac{a^2d}{bdx}$ and $\frac{a^2b}{bdx}$ by multiplying alternately by the quotients d and b , arising by the division of the denominators by the common divisor b . The other operations, with respect to numbers, are easily applied to algebraic quantities.

Addition and subtraction of fractions in species. The process is, in all respects, the same in species as in numbers. E. gr. Suppose it be required to add the fractions $\frac{a}{b}$ and $\frac{c}{d}$. These, when reduced to the same denomination, will be $\frac{ad}{bd}$ and $\frac{bc}{bd}$; consequently their sum is $\frac{ad+bc}{bd}$.

So, if the fraction $\frac{a}{b}$ were to be subtracted from $\frac{c}{d}$; having reduced them they will be $\frac{ad}{bd}$ and $\frac{bc}{bd}$, as before.

Their difference, therefore, is $\frac{bc-ad}{bd}$.

Multiplication and division of fractions in species. Here, too, the process is perfectly the same as in vulgar arithmetic. Thus, e. gr. suppose the factors, or fractions to be multiplied, $\frac{a}{b}$ and $\frac{c}{d}$; the product will be, $\frac{ac}{bd}$.

Or suppose the fractions, required to be divided, $\frac{ac}{bd}$ and $\frac{a}{b}$; the quotient will be, $\frac{ac}{bd} \times \frac{b}{a} = \frac{ac \times b}{a \times bd} = \frac{c}{d}$.

Hence, as $a = \frac{a}{1}$; the product of a into $\frac{c}{d}$, that is, of an integral quantity into a fraction, $\frac{c}{d} \times a = \frac{ac}{d}$. Whence it appears, that the numerator of the fraction is to be multiplied by the integer.

Hence, also, the quotient of $\frac{c}{d}$ by a , that is, of the broken quantity, divided by the whole one, $\frac{c}{d} \div a = \frac{c}{a \times d} = \frac{c}{ad}$.

Beside the common notion of a fraction, there is another necessary to be understood. Thus, Suppose $\frac{1}{2}$ of 20s. or a pound Sterling, were the fraction: this fraction, instead of three quarters of one pound, may be considered as a fourth part of three pounds; that is, by taking as many of the integers as the numerator expresses (viz. 3), and dividing them by 4, the denominator, for then the quotient of the same value will arise; for $4 \times 60s. = 120s.$ This shews the reason of that manner of expression used by geometers and algebraists, who read $\frac{a}{b}$, thus, a divided by b .

FRACTION, continued. is used for a fraction the denominator of which is a whole number with a fraction, the denominator of which is again a whole number and a fraction, and so on, whether this affection be continued ad infinitum, or whether the series breaks off after a finite number of terms. Thus,

$\frac{1}{2} + \frac{1}{3} + \frac{1}{4} + \frac{1}{5} + \frac{1}{6} + \frac{1}{7} + \frac{1}{8} + \frac{1}{9} + \frac{1}{10} + \frac{1}{11} + \frac{1}{12} + \frac{1}{13} + \frac{1}{14} + \frac{1}{15} + \frac{1}{16} + \frac{1}{17} + \frac{1}{18} + \frac{1}{19} + \frac{1}{20} + \frac{1}{21} + \frac{1}{22} + \frac{1}{23} + \frac{1}{24} + \frac{1}{25} + \frac{1}{26} + \frac{1}{27} + \frac{1}{28} + \frac{1}{29} + \frac{1}{30} + \frac{1}{31} + \frac{1}{32} + \frac{1}{33} + \frac{1}{34} + \frac{1}{35} + \frac{1}{36} + \frac{1}{37} + \frac{1}{38} + \frac{1}{39} + \frac{1}{40} + \frac{1}{41} + \frac{1}{42} + \frac{1}{43} + \frac{1}{44} + \frac{1}{45} + \frac{1}{46} + \frac{1}{47} + \frac{1}{48} + \frac{1}{49} + \frac{1}{50} + \frac{1}{51} + \frac{1}{52} + \frac{1}{53} + \frac{1}{54} + \frac{1}{55} + \frac{1}{56} + \frac{1}{57} + \frac{1}{58} + \frac{1}{59} + \frac{1}{60} + \frac{1}{61} + \frac{1}{62} + \frac{1}{63} + \frac{1}{64} + \frac{1}{65} + \frac{1}{66} + \frac{1}{67} + \frac{1}{68} + \frac{1}{69} + \frac{1}{70} + \frac{1}{71} + \frac{1}{72} + \frac{1}{73} + \frac{1}{74} + \frac{1}{75} + \frac{1}{76} + \frac{1}{77} + \frac{1}{78} + \frac{1}{79} + \frac{1}{80} + \frac{1}{81} + \frac{1}{82} + \frac{1}{83} + \frac{1}{84} + \frac{1}{85} + \frac{1}{86} + \frac{1}{87} + \frac{1}{88} + \frac{1}{89} + \frac{1}{90} + \frac{1}{91} + \frac{1}{92} + \frac{1}{93} + \frac{1}{94} + \frac{1}{95} + \frac{1}{96} + \frac{1}{97} + \frac{1}{98} + \frac{1}{99} + \frac{1}{100} + \frac{1}{101} + \frac{1}{102} + \frac{1}{103} + \frac{1}{104} + \frac{1}{105} + \frac{1}{106} + \frac{1}{107} + \frac{1}{108} + \frac{1}{109} + \frac{1}{110} + \frac{1}{111} + \frac{1}{112} + \frac{1}{113} + \frac{1}{114} + \frac{1}{115} + \frac{1}{116} + \frac{1}{117} + \frac{1}{118} + \frac{1}{119} + \frac{1}{120} + \frac{1}{121} + \frac{1}{122} + \frac{1}{123} + \frac{1}{124} + \frac{1}{125} + \frac{1}{126} + \frac{1}{127} + \frac{1}{128} + \frac{1}{129} + \frac{1}{130} + \frac{1}{131} + \frac{1}{132} + \frac{1}{133} + \frac{1}{134} + \frac{1}{135} + \frac{1}{136} + \frac{1}{137} + \frac{1}{138} + \frac{1}{139} + \frac{1}{140} + \frac{1}{141} + \frac{1}{142} + \frac{1}{143} + \frac{1}{144} + \frac{1}{145} + \frac{1}{146} + \frac{1}{147} + \frac{1}{148} + \frac{1}{149} + \frac{1}{150} + \frac{1}{151} + \frac{1}{152} + \frac{1}{153} + \frac{1}{154} + \frac{1}{155} + \frac{1}{156} + \frac{1}{157} + \frac{1}{158} + \frac{1}{159} + \frac{1}{160} + \frac{1}{161} + \frac{1}{162} + \frac{1}{163} + \frac{1}{164} + \frac{1}{165} + \frac{1}{166} + \frac{1}{167} + \frac{1}{168} + \frac{1}{169} + \frac{1}{170} + \frac{1}{171} + \frac{1}{172} + \frac{1}{173} + \frac{1}{174} + \frac{1}{175} + \frac{1}{176} + \frac{1}{177} + \frac{1}{178} + fractured bone, the bleeding is required, to prevent any lodgment of blood on the part aggrieved, by the violence upon the fibres.

With regard to the regimen and general treatment of the patient in these circumstances, we may observe, that, when a large bone is broken, his diet should in all respects be the same as in an inflammatory fever: he should likewise be kept quiet and cool, and his body open by emollient clysters, or by food of an opening quality. However, persons that have been accustomed to high living should not be suddenly reduced to a low diet. It will generally be necessary to bleed the patient immediately after a fracture, especially if he be young, of a full habit, and has received any contusion: and if the patient be very feeble, bleeding may be repeated the next day. In fractures of the ribs, bleeding is peculiarly necessary; when any of the large bones, by which the body is supported, are broken, the patient should keep his bed for several weeks; reclining in an easy posture. When a fracture is accompanied with a wound, it must be dressed in all respects as a common wound. When the fractured bone is much shattered, it will sometimes be necessary to have the limb taken off, lest a gangrene or mortification ensue.

Fracture of the carpus, or wrist, clavicle, cubiti, finger, foot, humerus, jaw, leg, metacarpus, neck, nose, or scapula, at scapula, patella, ribs, scapula, skull, sternum, thigh, and vertebra. See WRIST, CLAVICLE, CUBITUS, &c.

Fracture, capillary. See CAPILLATION.

Fractured limb, extraneous. See EXTENSION.

FRÆNA, a word used by some anatomical writers, as a name for the lockets of the teeth.

FRÆNUM, or **FRÆNUM**, *brille*, in *Anatomy*, a name given to divers ligaments, from their office in retaining and curbing the motions of the parts they are fitted to.

FRÆNUM lingue, or *brille of the tongue*, is a membranous ligament, which ties the tongue to the os hyoides, larynx, fauces, and lower part of the mouth.

In some subjects the *frænum* runs the whole length of the tongue, to the very tip; in which cases, if it were not cut, it would take away all possibility of speech. See *TONGUE tied*.

FRÆNUM of the penis is a slender ligament, whereby the prepuce is tied to the lower part of the glans of the PENIS.

Nature varies in the make of this part; it being so short in some, that unless divided, it would not admit of perfect erection. There is also a kind of little *frænum*, fastened to the lower part of the CLITORIS.

FRAGARIA. See STRAWBERRY.

FRAIGHT, or *FRIGHT*, in *Navigation and Commerce*, the hire of a ship, or of a part of it, for the conveyance and carriage of goods from one port, or place, to another, or the sum agreed on, between the owner and the merchant, for the hire and use of a vessel.

The word is formed of the French *frat*, signifying the same thing; or from *frat*, of *fratrum*, an arm of the sea: though others chuse to derive it from the German *fracht*, or the Flemish *wacht*, signifying carriage.

The freight of a vessel is usually agreed on either at the rate of so much for the voyage, or by the month, or per ton.

Freighting, or lading out vessels on freight, or hire, is one of the principal articles in the trade of the Hollanders: they are the carriers of all the nations of Europe, and their purveyors; notwithstanding that their country produces little or nothing, and that they are forced to have every thing necessary for the building of a vessel from other countries.

The principal laws and rules relating to freighting are, that if a whole vessel be hired, and the merchant, or person who hires it, do not give it its full load, or burthen, the master of the vessel cannot, without his consent, take in any other goods, without accounting to him for freight.

That though the merchant do not load the full quantity of goods agreed on in the charter-party, yet he shall pay the whole freight; and if he load more, he shall pay for the excess.

If a time be appointed by charter-party, and either the ship be not ready to take in, or the merchant to put on board, the parties are at liberty, with remedy by action for the detriment.

If part be on board, and some misfortune prevent the merchant's sending the whole in time, the master may contract with another, and have freight as damage for the time they were on board longer than limited.

On the other hand, if the vessel is not ready, the merchant may ship the remainder of his goods aboard another, and recover damages against the first master or owners: therefore, by the law marine, charter, or other

Vol. II. N° 141.

notorious necessity, will excuse the master, but he loses his freight till he breaks ground. But if the merchant be in fault, he must answer the damage, or be liable to maintain the crew ten days; and, if after that, the full freight; if damage afterwards, it is the merchant's risk: but by the common law, while the goods are on board, the master must see them forth-coming.

If goods are fully laded, and the ship hath broke ground, but the merchant afterwards declines the adventure, and unloads again, by the law marine the freight is due.

If a set time be agreed upon between the merchant and master, to begin and end the voyage, it may not be altered by the supercargo, without special commission; and if a master shall fail on his voyage, after the time agreed on for his departure, and damage happens afterwards, he shall make it good. If a ship be freighted from one port to another, thence to a third, &c. and so home to the port whence the first filled (commonly called a trading voyage), the whole is one and the same voyage, if performed according to the charter-party. If the ship be freighted out and in, no freight is due till the voyage is performed; if, therefore the ship perish coming home, the whole freight is lost.

The master may set ashore such goods as he finds in his vessel, which were not notified to him; or take them at a higher rate than was agreed on for the rest. But if the master freight his ship, and afterwards secretly take in other goods, he loses his freight; and if any of the freighter's goods should, for the ship's safety, be cast overboard, the rest shall not be subject to AVERAGE, but the master must make it good.

If a ship be stopped or detained in its course, either through the master's, or the merchant's default, the detainer shall be accountable to the other. Thus, if the freighter load the ship with prohibited goods, he shall answer the freight contracted; but if the ship put into any other port than the is freighted to, the master shall answer damage to the merchant; but if forced in by storm, enemy, or pirates, he must then fall to the stipulated port at his own costs.

If the master be obliged to rest his vessel during the voyage, the merchant shall wait, or else pay the whole freight: if the vessel could not be refitted, the master is obliged to hire another immediately, otherwise only to be paid his freight in proportion to the part of the voyage performed; though, in case the merchant prove that the vessel, at the time it set sail, was not capable of the voyage, the master must lose his freight, and account for damages to the merchant.

Freight shall be paid for merchandizes which the master was obliged to sell for victuals, or renting, or other necessary occasions, paying for the goods at the rate the rest were sold at, where they were landed. In case of a prohibition of commerce with the country whither the vessel is bound, so that it is obliged to be brought back again, the master shall only be paid freight for going.

And if a ship be stopped or detained in its voyage, by an embargo by order of the prince, there shall neither be any freight paid for the time of the detention, in case it be hired per month; nor shall the freight be increased, if hired for the voyage; but the pay and the victuals of the sailors, during the detention, shall be deemed AVERAGE.

The master shall take no freight for any goods lost by shipwreck, plundered by pirates, or taken by the enemy, unless the ship and goods be redeemed; in which case he shall be paid his freight to the place where he was taken, upon contributing to the redemption.

The master shall be paid his freight for the goods fixed from shipwreck; and in case he cannot get a vessel to carry them into the place where they were bound, he shall be paid in proportion to the part of the voyage already gone. The ship's lading, in consideration of law, is tacitly obliged for the freight; this being in point of payment, preferred before any other debts to which the goods laden are liable, though such were precedent to the freight, because the goods remain, as it were, bailed for the same.

The master may not detain any merchandize in his vessel, in default of payment of freight; though he may order them to be seized any time, or any where afterwards. If merchandizes in casks, as wines, oils, &c. have so run out in carriage, that the vessels are left empty, or almost empty, the merchant may relinquish them, and the master be obliged to take them for their freight; though this does not hold of any other goods damaged, or diminished of themselves, or through accidents.

Freight is also used for the burthen, or lading of a ship, or the cargo of goods, &c. which she has on board.

Freight is also a duty of fifty sels per ton, paid to the

7 R crown

crown of France by the masters of all foreign vessels, at their entrance into and going out of the ports and havens of that kingdom. And note, that all vessels not built in France, however they may belong to the subjects of France, are reputed foreigners, and subject to this impost, unless it be made appear, that two thirds of the ship's crew are French.

By the eleventh article of the treaty of commerce, concluded at Utrecht between England and France, this duty of fifty sols per ton was to have been remitted the English; and at the same time, the duty of five shillings sterling to have been suppressed in favour of the French; but the execution of that article, as well as the tariff settled between the two nations, has been suspended.

The Dutch, however, and the Hanse towns, are exempted from the duty of *fracht*.

FRAIL, a baker of rullies, or of the like matter, wherein to pick up *figs*, raisins, &c.

FRAIL also denotes a certain quantity of raisins, about seventy-five pounds.

FRALSK, in *Particulation*, a kind of defence, consisting of pointed stakes, driven parallel to the bastion, into the retrenchments of a camp, a half moon, or the like, to ward off and prevent any approach or scalade.

Frails differ from *palisades* chiefly in this, that the latter stand perpendicular to the horizon, and the former jet out parallel to the horizon, at least obliquely, being usually made a little sloping, or with the points hanging down. *Frails* are chiefly used in retrenchments, and other works thrown up of earth: sometimes they are found under the parapet of a rampart, serving instead of the cordon of stone used in these works.

FRAMING of a *bastion*, is the lining it all round with pikes in case of being charged by a body of horse.

FRAMBOISE, a name used by some for the *rubus* or black-berry bush. See *RASPBERRY*.

FRAME, in *Tramery*, &c. a kind of case, wherein a thing is set, or inclosed, or even supported, as a window frame, a frame of a picture, of a table, &c.

FRAME is also a machine, used in divers arts. The printers frame is more usually called a *case*.

The founders frame is a kind of lodge, inclosing a board, which being filled with wetted lead, serves as a mould to cast their work in. See *FOUNDER*.

FRAME is more particularly used for a sort of loom, whereon artificers stretch their linsens, silks, linens, &c. to be embroidered, quilted, or the like.

FRAME, among *Painters*, &c. is a kind of square, composed of four long pieces, or slips of wood, jointed together; the intermediate space whereof is divided by little strings or threads, into a great number of little squares, like the meshes of a net; and for that reason sometimes called *reticula*.

Its use is in reducing of figures from great to small, or augmenting their size from small to great. See *DESCENDING*.

FRAMING of a *house*, all the timber-work therein, viz. the *carcase*, *flooring*, *partitioning*, *roofing*, *clinging*, *beams*, *chimneys*, &c.

FRAMPOLLE *ferm*, a privilege enjoyed by the tenants of the manor of Writtle, in Essex; whereby they are entitled to the wood growing on the fence; and as many trees or poles as they can reach from the top of the ditch with the helve of an ax, toward the repair of their fence.

The chief justice Brampton, whilst steward of this court, acknowledged he could not find out the reason why these fences were called *frampole*. It may come from the Saxon *ferenfol*, *prestible*; or may be a corruption of *frampole*, because the poles are free for the tenant to take.

FRANC. See *FRANK*.

FRANCA, in *Botany*, the name given by Micheli to a genus of plants, since called by Linnaeus *FRANKERIA*.

FRANCHISE, a privilege or exemption from ordinary jurisdiction.

FRANCHISE is also used for an immunity from the ordinary tributes and taxes.

This is either real, or personal; that is, either belonging immediately to the person, or accruing on account of this or that place, or office of IMMUNITY.

These *franchises*, being royal privileges, or branches of the king's prerogative, subsisting in the hands of a subject, are derived from the crown by grant or charter, and, in some cases, are held by prescription and usage. They may be vested either in natural persons, or bodies politic in one man, or in many; but the same identical *franchise* that has before been granted to one, cannot be bestowed on another, for that would prejudice the former grant. The principal kinds of *franchises* are the following: to be a *COUNTY palatine* is a *franchise* vested in a number of persons. It is likewise a *franchise* for a num-

ber of persons to be incorporated, and subsist as a body politic, with a power to maintain perpetual succession, and do other corporate acts; and each individual member of such corporation is also said to have a *franchise* or freedom. Other *franchises* are to hold a court leet; to have a manor or lordship; or, at least, to have a lordship paramount; to have walls, weirs, cressets, trays, treasure-trove, royal-fish, forfeitures, and decodans; to have a court of one's own, or liberty of holding pleas and trying causes; to have the cognizance of pleas, which is a still greater liberty, being an exclusive right, so that no other court shall try causes arising within that jurisdiction; to have a bailiwick, or liberty exempt from the sheriff of the county, wherein the grantee only and his officers are to execute all process; to have a fair or market, with the right of taking toll, either there or at any other public places, as bridges, wharfs, and the like; which toll must have a reasonable cause of commencement, else the *franchise* is illegal and void; or, lastly, to have a forest, chase, park, warren or fishery, endowed with privileges of royalty. See the several articles above recited.

FRANCHISE, *whimsie* of. See *OGO* *narrants*.

FRANCHISE *whimsie* of, is remedied by suing for damages, by a special action on the case; or, in case of toll, the injured person may take a distress if he pleases.

FRANCHISE is also used for an asylum, or sanctuary, where people are secure of their persons, &c.

Churches and monasteries in Spain are *franchises* for criminals; so were they anciently in England, till they were abused to such a degree, that there was a necessity for abolishing the custom.

One of the most remarkable expropriations made by Charlemagne in his palace of Héristal, in 799, was that relating to the *franchises* of churches. The right of *franchise* was held to sacred, that even the less religious kings offered it to a degree of irreligiosity, but to such excess in time was it carried, that Charlemagne resolved to reduce it. Accordingly he issued any provision being carried to criminals retired into churches for refuge.

FRANCHISE of quarters, is a certain space, or district at Rome, wherein are the houses of the ambassadors of the princes of Europe; and where such as retire, cannot be arrested, or seized by the sheriff, or sergeants, nor prosecuted at law.

The people of Rome look on this as an old usurpation, and a scandalous privilege, which amends, out of a jealousy of their power, carried to a great length in the fifteenth century, by enlarging insensibly the dependencies of their palaces or houses, within which the right of *franchise* was anciently confined. Several of the popes, Julius III. Pius XIV. Gregory XIII. and Sixtus V. published bulls and ordinances against this abuse, which had refused to considerable a part of the city from their authority, and rendered it a retreat for the most abandoned persons.

At length Innocent XI. expressly refused to receive any more ambassadors, but such as would make a formal renunciation of the *franchise* of quarters.

FRANCHISE *royal*, is a place where the king's writ runs not; as at Chelsea, and Durham; and anciently at Tyndal, and Hexhamshire in Northumberland. But Bracton says, that a *franchise* *royal* is where the king grants to one and his heirs an exemption of toll, &c. See *FRANCHISE*.

FRANCHISING. See *ENFRANCHISEMENT*, and *MANUMISSION*.

FRANCIGENA, or *FRANCHMAN*, in our *Ancient Customs*, was a general appellation of all foreigners; i. e. all persons who could not prove themselves Englishmen.

FRANCISCANS, in *Ecclésiast. History*, are religious of the order of St. Francis, founded by him in the year 1209. Francis was the son of a merchant of Assisi, in the province of Umbria, who, having led a dissolute life, was reclaimed by a fit of sickness; and afterwards fell into an extravagant kind of devotion, that looked less like religion than alienation of mind. Soon after this, viz. in the year 1208, bearing the pallage repeated, Matt. x. 9, 10. in which Christ addresses his apostles, *Provide neither gold, nor silver, &c.* he was led to consider a voluntary and absolute poverty as the essence of the Gospel, and to prescribe this poverty as a sacred rule both to himself and to the few that followed him. This new society, which appeared to Innocent III. extremely adapted to the present state of the church, and proper to relieve its declining credit, was solemnly approved and confirmed by Honorius III. in 1223, and had made a considerable progress before the death of its founder in 1226. Francis, through an excessive humility, would not suffer the monks of his order to be called *Frater*, i. e. *brother* or *frater*, but *fratru*, i. e. *little brethren*, or *fratru*, by which denomination they still continue to be distinguished. They are also called *Gry Friars*, on account of the colour of their clothing; and *Cordeliers*, &c.

&c. The *Franciscans* and *DOMINICANS* were zealous and active friends to the papal hierarchy, and, in return, were distinguished by peculiar privileges and honourable employments. The *Franciscans*, in particular, were invested with the treasure of ample and extensive indulgences, the distribution of which was committed to them by the pope, as a means of subsistence, and a rich indemnification for their voluntary poverty. In consequence of this grant, the rule of the founder, which absolutely prohibited both personal and collective property, so that neither the individual nor the community were permitted to possess either land, revenue, or any worldly goods, was considered as too strict and severe, and dispensed with soon after his death. In 1231, Gregory IX. published an interpretation of this rule, mitigating its rigour; which was further confirmed by Innocent IV. in 1245, and by Alexander IV. in 1257. These milder alterations were zealously opposed by a branch of the *Franciscans*, called the *spirituals*; and their complaints were regarded by Nicholas III. who, in 1279, published a famous constitution, confirming the rule of St. Francis, and containing an elaborate explication of the maxima it recommended, and the duties it prescribed. In 1285, Matthew of Aquasparta, being elected general of the order, discouraged the ancient discipline of the *Franciscans*, and indulged his monks in abandoning even the appearance of poverty; and this conduct inflamed the indignation of the *spiritual* or austere *Franciscans*; so that from the year 1290, seditions and schisms arose in an order, that had been so famous for its pretended disinterestedness and humility. Such was the enthusiastic fervour of the *Franciscans*, that they impudently maintained, that the founder of their order was a second Christ, in all respects similar to the first; and that their institution and discipline were the true gospel of Jesus. Accordingly, Albizzi, a *Franciscan* of Pisa, published a book, in 1383, with the applause of his order, entitled, *The Book of the Conformities of St. Francis with Jesus Christ*. In the beginning of this century the whole *Franciscan* order was divided into two parties; the one, embracing the severe discipline and absolute poverty of St. Francis, were called *spirituals*; and the other, who insisted on mitigating the austere injunctions of their founder, were denominated *brothers of the community*. These wore long, loose, and good habits, with large hoods; the former were clad in a straight, coarse, and short dress, pretending, that this dress was enjoined by St. Francis, and that no power on earth had a right to alter it. Neither the moderation of Clement V. nor the violence of John XXII. could appease the tumult, occasioned by these two parties; however, their rage subsided from the year 1320. In 1368 these two parties were formed into two large bodies, comprehending the whole *Franciscan* order, which subsist to this day; viz. the *CONVENTUAL brothers*, and the *brothers of the OBSERVANCE or abstinence*, from whom sprang the *CAPUCHINS* and *RECOLLECTS*. *Moshi. Eccl. Hist. vol. III. See Notes of St. CLARE and FRANKS.*

The general opinion is, that the *Franciscans* came into England in the year 1224, and had their first house at Canterbury, and their second at London; but there is no certain account of their being here till King Henry VII. built two or three houses for them. At the dissolution of the monasteries, the conventual *Franciscans* had about fifty-five houses, which were under seven custodies or wardenships; viz. three of London, York, Cambridge, Bristol, Oxford, Newcastle, and Worcester.

FRANCOLIN, in Ornithology. See **ATTAGOU**.

FRANGIPANI, an exquisite kind of perfume, frequently given to the leather wherof gloves, pairs, bags, &c. are made.

It takes its name from a Roman nobleman, of the ancient family of *Frangipani*, who was the inventor of it. There is also a kind of perfumed liquor of the same denomination, said to have been invented by a grandson of *Murio Frangipani*; and also a perfumed kind of *ras solis*, called by the same name.

FRANGULA, in Botany. See *Berry-bearing ALDER*.

FRANK, or **FRANCE**, a term literally signifying free and open, or exempt from public impositions and charges; as *frank confession*, *frank fair*, *frank letter*, &c.

The term *frank* is much used in our ancient customs and tenure; where it receives various particular modifications and meanings, according to the words it is compounded with; as,

FRANK alien, or *allodium*, is a land, tenement, or demesne, that is not held of any superior lord.

FRANK alms, or *free alms*, is a tenure of lands or tenements bestowed on God; that is, given to such people as devote themselves to the service of God, in pure and perpetual alms; or, it is a tenure, whereby a religious corporation, aggregate or sole, holdeth lands of the donor or them and their successors for ever.

Whence the feoffers, or givers, cannot demand any territorial service, so long as the land remains in the hands of the feoffees.

The service which the feoffees were bound to render for these lands is not certainly defined; but only, in general, to pray for the souls of the donor and his heirs, dead or alive; and, therefore, they did not fealty, which is incident to all other services but this, because this divine service was of a more exalted nature. This is the tenure, by which all the ancient monasteries and religious houses held their lands; and by which the proclial clergy, and many ecclesiastical and eleemosynary foundations, hold them at this day. This was an old Saxon tenure, and continued under the Norman revolution, on account of the respect shewn to religion, and religious men, in ancient times; and for this reason, tenants in *frank alms* were discharged of all other services, except the *tristitia neffitia*, of repairing the highways, building castles, and repelling invasions. And this tenure is still distinct from all others, being not in the least feudal, but merely spiritual; for, if the service be neglected, the law gives no remedy by distress or otherwise to the lord of whom the lands are holden; but merely a complaint to the ordinary or visitor to correct it.

Briton mentions another kind of land given in alms, but not free alms; the tenants being tied to certain services to the feoffers: as to sing so many masses, distribute such a sum in alms, and the like; and this tenure by divine service differs from the former, because for this, unperformed, the lord might distrain, without any complaint to the visitor. All such donations are now out of use; for since the statute of *quia emptores*, 18 Edw. I. none but the king can give lands to be holden by this tenure.

FRANK bank. See **FREE bank**.

FRANK chase denotes liberty of free chase, in a circuit adjoining to a forest, on account of which, men, though they have land of their own within that compass, are forbidden to cut down wood, without the view of the forester; though it be their own demesne. See **CHASE**.

FRANK fee, *feudum francum*, as defined by Broek, is that which is in the hands of the king, or lord of the manor, being ancient demesne of the crown.

FRANK fee, *feudum liberum*, according to some, denotes that for which no service is performed to any lord. According to Fachin, lib. vii. cap. 39. lands held in *frank fee* were exempted from all services, except homage. In contradistinction to that in the tenants hands, which is only ancient demesne.

In the reg. of writs, *frank fee* is said to be that which a man holds at common law to him, and his heirs; and not by such service as is required in ancient demesne, according to the custom of the manor.

It is added, that the land in the hands of king Edward the Confessor, at the making of Domesday book, is ancient demesne; and all the rest, *frank fee*. On which footing, all the lands of the realm are either ancient demesne, or *frank fee*.

Others define *frank fee* to be a tenure in fee-simple, of lands pleadable at common law; and not in ancient demesne. See **FEU**.

FRANK farm, *firma libera*, denotes lands or tenements, wherein the nature of the fee is changed, by feoffment, from knight's service, to a certain yearly service; and whence neither homage, wardship, marriage, nor relief, may be demanded; nor any other service, not contained in the feoffment. See **FEU farm**, and **SOCAGE**.

FRANK fold is where the lord hath the benefit of folding his tenants sheep, within his manor, for the manuring of his land.

FRANK language, or *lingua FRANCA*, is a kind of jargon, spoken on the Mediterranean, and particularly throughout the coasts and ports of the Levant; composed of Italian, Spanish, French, vulgar Greek, and other languages.

The *lingua Franca* is the trading language; and is thus called from the *Franks*, a common appellation given in the Levant to all the European merchants and traders, who come thither to traffick.

In this language, if it may be so called, nothing but the infinite mood of each verb is used; this serving for all the tenses and moods of the conjugation; and yet this lame, mutilated diction, this barbarous medley, is learnt and understood by the merchants and mariners of all nations who repair thither.

FRANK law, *lex libera*, is the benefit of the free and common law of the land.

He that for any offence, as conspiracy, &c. loseth his *frank law*, incurs these inconveniences: 1. That he may not be impeached on any jury or affize; or otherwise used as an evidence, or witness to the truth. 2. That if he have any thing to do in the king's court, he must not approach it in person, but appoint his attorney. 3. That his

his lands, goods, and chattels, be seized into the king's hands; and his lands be cleared, his trees rooted up, and his body committed to custody.

FRANK letters, or letters free of purveyance. The privilege of such letters was claimed by the house of commons in 1660, when the first legal settlement of the present **POST-OFFICES** was made; but afterwards dropped on a private allowance from the crown, that this privilege should be allowed the members. Accordingly, a warrant was constantly issued to the post-master general, directing the allowance thereof to the extent of two ounces in weight; till at length it was expressly confirmed by statute 4 Geo. III. cap. 24. which adds many new regulations, rendered necessary by the abuses crept into the practice of franking; whereby the annual amount of *frank letters* had gradually increased from 23,000l. in 1715, to 170,700l. in 1762. Blackst. Com. vol. i. p. 322.

FRANK marriage, liberum matrimonium, is a tenure in tail fee, whereby lands, or tenements, are held to a person and his wife, and the heirs of their bodies, on condition of doing fealty to the donor, till the fourth degree of consanguinity between the issues of the donor and donee.

Fealty gives this reason, why the heirs do no service, till the fourth degree: *ad dominum, vel eorum heredes, fealty est recipiendum a rebus in perpetuum*; and why, in the fourth descent, they shall do service to the donor, *quia in quarto gradu succentur premissis quod terra ipsius defuncti barones donatarum reversionem.*

FRANK marriage is expressed, by Bracton, to be that where the donor intends, that the land thus bestowed shall remain quiet, and free from all secular service that might be annexed to the fee; so that he who gave it shall claim no manner of service from it, until the third heir, and the fourth descent, or degree; reckoning the donee in the first degree, his heir in the second, the heir of him in the third, and his, again, in the fourth; but afterwards the same land to become subject to all the former services; as being then supposed to revert to the lord, for want of heirs.

The lands otherwise given in marriage, viz. *feudum aliquod*, were with a reservation of the services due to the lord, which the donee and his heirs, were bound to perform for ever; until homage was not to commence till the fourth degree, when both service and homage were to be enjoined for ever.

FRANK-pledge signifies a pledge or security for the behaviour of a freeman, called also **FRANKBURG.**

The ancient custom of England, for preservation of the public peace, was, that every free-born man, at fourteen years of age (religious persons, clerics, knights, and their eldest sons, excepted) should find surety for his truth towards the king and his subjects, or else to be kept in prison.

Accordingly, a number of neighbours became interchangeably bound for each other, to see each man of their pledge forthcoming at all times; or to answer for the offence committed by any one gone away, so that whenever one offended, it was precisely inquired in what *pledge* he was; and then those of the pledge either brought him forth within one and thirty days to his answer; or they satisfied for his offence.

This custom was called *frank-pledge*; and the circuit it extended to, *decennium*, because it usually consisted of ten households; and every person thus bound for himself and neighbours was called a *decennarius*. See **DECINERS.**

In observance of this custom, the sheriffs at every county-court did from time to time take the oaths of young persons, as they arrived at the age of fourteen; and see they were settled in one *decennium*, or *decennium*, or another; whereupon this branch of the sheriff's office and authority was called *visus franci plegii*, i. e. *visus franci plegii*.

Omnes homines, sine liberis, sine servis, aut ipsi, vel debet esse in franco plegio, aut de aliquo mancipio, nisi sit aliquis iusticiarius de locis in decennium, qui non potest se teneat ad unum quem ad alium, vel qui debet esse plegius pro franco plegio, nisi de plegio, vel ordinem, vel liberum tenementum, vel in civitate rem committens, &c. Bracton, lib. iii.

Tract. de Corona, cap. 12.

FRANK service. See **SERVICE.**

FRANK, or FRANK, also denoted an ancient coin, struck, and current in France; thus called from its impression, which represented a Frenchman, sometimes on horseback, and sometimes on foot.

The *frank* was either of gold or silver: the first was worth somewhat more than the *écu d'or*, or gold crown. See **CROWN.**

The second was a third of the first; but these coins have been long diffused.

The term *frank*, however, is still retained as the name of a money of account. In this sense it is equivalent to a livre, or twenty sols, or a third of a French crown.

Thus they say indifferently, a hundred *franks*, or a hundred *livres*.

FRANKENIA, in *Botany*, the name given by Linnaeus to a genus of plants of the *hebanaria monogyna* class, called by Michx. *franka*. The perianthium is permanent, and is composed of one leaf of an oblong tubular form, divided into five segments at the edge; the flower consists of five petals, the ungues of which are narrow, and of the length of the cup, and the tops roundish and expanded; the stamina are ten filaments, longer than the tube; the apices are simple; the germ of the pistil is roundish; the style is capillary, and of the length of the stamina; the stigma is divided into six parts; the fruit is an oval capsule covered with the cup, and formed of three valves, but containing only one cell, in which are a great number of small seeds of an oval figure. There are three species.

FRANKINCENSE, or simply **INCENSE**, an odiferous aromatic gum or resin, anciently burnt in temples, as a perfume, and now used in pharmacy as an agglutinant and strengtheners.

The word is formed from the Latin *incensum*, burnt; as alluding to its ancient use in temples.

Frankincense distils from incisions made in a tree called *arborescens*, during the heats of summer. But, notwithstanding the great use of this gum, both in the ancient religion, and the modern medicine, the tree that produces it, or even the place where the tree grows, is but little known.

The most common opinion has always been, that it was brought from Arabia Felix, and was found near the city of Saba; whence its epithet *Sabaicum*; and yet the name *alibanum*, which it sometimes also bears, seems to intimate, that there are of these thustaceous or incense-bearing trees in the Holy Land near mount Lebanon. And travellers are positive, that there are others in the East Indies.

Not are we left at a loss as to the form or kind of the tree from which it flows. Pliny contents himself to say, that it at first resembles the pear tree; then the mulberry tree; then the laurel; but that in reality it is a kind of turpentine-tree.

Frankincense is usually divided into *male* and *female*.

The *male incense*, thus *masculinum*, called also *alibanum*, is in fair white bits, or tears, a little yellowish, of a bitter disagreeable taste; and when chewed, it promotes the flux of saliva, which becomes white. When laid on coals, or a red-hot iron, it flames and burns with a strong and not unpleasant smell. On trituration with water, the gummy part dissolves into a milky liquor, which deposits a resinous matter, and being gently insinuated, leaves a yellow extract, retaining the greatest part of the smell as well as taste of the *alibanum*. Rectified spirit dissolves less than water.

It is called *male* in respect of its tears, which are larger than those of the common or female.

That brought from the Indies is not near so good as that from Arabia, or mount Lebanon; it is feminine, called *incense of Arabia*; though it be not brought from that city. It is often in a mass, but sometimes in loose drops or tears; somewhat reddish, and bitter to the taste. Some sell this for the true bellium.

Male incense, or *alibanum*, is an ingredient in divers Galenical and chemical preparations: it warms, dries, and binds; and is used not only in divers distillations of the head and breast, but in vomitings, diarrhoeas and dysenteries. The dose is from a scruple to a dram or more. Externally it is applied to strengthen the brain, and heal wounds. Some use it to alluage the tooth-ach; but it is apt to spoil the good teeth.

As for *female incense*, or *frankincense*, authors describe it to be softer, and more resinous, but of less virtue than the former. This common *frankincense* is brought to us in little globes or masses, of a brownish or yellowish colour on the outside, internally whitish, and variegated with whitish specks. It is supposed to be the produce of the plant that yields the common turpentine, and to concreted upon the surface of the turpentine juice, soon after it has issued from the tree. This resin has a bitterish, acrid, unpleasant taste, and no considerable smell; it dissolves totally in rectified spirit, but is scarcely acted upon by watery menstrua. It may be looked upon as a mild corroborant; though at present it is little otherwise made use of than as an ingredient in theriaca, and externally in plasters. Lewis, Mat. Med.

Bark of incense, *cortex thuris*, is the bark of the tree whence the *incense* flows, which has the same qualities with the *incense* itself.

There is another bark brought from the Indies, called also *bark of incense*, and sometimes *frank incense*, because the Jews make frequent use thereof in their perfume: this is the *cortex electaria*.

Manna of incense is the flour or farina of *incense*, occasioned

tioned by the frictions of the grains against each other in the sacks wherein they carry it.

There is also a foot of *incense*, which is a preparation of it, burnt like resin to make lamp-black.

Frankness was formerly burnt in the temples of all religions, to do honour to the divinity that were there adored. Many of the primitive Christians were put to death, because they would not offer incense to idols.

In the Romish church they still retain the use of incense in some of their ceremonies; always at high-mass, and at the elevation of the host at vespers; and at solemn funerals, bestowing it on such persons as they would honour, as on prelates, &c. and sometimes also on the people.

FRANKS, *FRANCE*, *FRANKIE*, or *FRANQUIS*, a name which the Turks, Arabs, Greeks, &c. give to all the people of the western parts of Europe.

The appellation is commonly supposed to have had its rise in Asia, at the time of the crusades; when the French made the most considerable figure among the crusaders; from which time the Turks, Saracens, Greeks, Abyssinians, &c. used it as a common term for all the Christians of Europe; and called Europe itself *Frankistan*.

The Arabs and Mahometans, says M. d'Herbelot, apply the term *Franks* not only to the French (to whom the name originally belonged) but also to the Latins and Europeans in general.

But E. Goss, in his notes on Condus, cap. 6. n. 43. furnishes another origin of the appellation *Franks*, of greater antiquity than the former. He observes, that the Greeks at first confined the name to the *Franks*, i. e. the German nations, who had settled themselves in France or Gaul; but afterwards they gave the same name to the Apulians and Calabrians, after they had been conquered by the Normans; and at length the name was farther extended to all the Latins.

In this sense is the word used by divers Greek writers; as Commenas, &c. who to distinguish the French, call them the *western Franks*.

Da-Cange adds, that about the time of Charlemagne, they distinguished eastern France, western France, Latin, or Roman France, and German France, which was the ancient France, afterwards called *Francia*.

FRAPPING, in *Somnology*, denotes the act of crossing and drawing together the several parts of a tackle, or other complication of ropes, which had been already frayed to their utmost extent, resembling the operation of breaking up a drum, &c. The *frapping* increases the tension, and adds to the security acquired by the purchase. Hence the cat-harpings are no other than *frapping* to the ground.

FRAPPING a ship, is the act of passing three, four, or five turns of a cable round the hull, or frame of a ship, in the middle, to support her in a great storm, when it is apprehended she is not strong enough to resist the violent efforts of the sea. This is seldom used, except in old ships. Falconer.

FRASSETUM, in our *Old Writers*, is taken for a wood, or woody ground, where ash grows. 1 Inst. 4.

The word is a corruption of the Latin *fraxinetum*, which signifies the same.

FRATERIA, of *frater*, *brother*, a fraternity, brotherhood, or society of religious persons, who were bound to pray for the good health and life, &c. of their living brethren, and the souls of those that were dead. In the statutes of the cathedral church of St. Paul, London, collected by Ralph Baldock, dean, 1296, there is one chapter *De frateria benedictorum ecclesie S. Pauli*, &c.

FRATECULA, in *Zoology*, a name by which Gefner and Aldrovand have called the *amur arctia clogis*. See *Puffin*.

FRATERNITY, *fraternalis*, the relation or union of brothers, friends, partners, and associates, &c.

FRATERNITY, in a civil sense, is used for a guild, association, or society of persons, united into a body, for some common interest or advantage.

For the origin, use, &c. of *fraternities*, see *COMPANY* and *GUILD*.

FRATERNITY, in a religious sense, is a society of persons meeting together to persons, some exercises of devotion, or divine worship.

In the Romish church, such *fraternities* are very numerous and considerable, being most of them established by royal patents; as the *fraternity of the ROSARY*; the *fraternity of the SCAPULARY* of St. Francis's Cord; see *CORDELIERS* and *FRANCISCANS*. The bishop may hinder the establishment of any such *fraternity* in his diocese.

At Rome there is a *fraternity*, called the *archi-fraternity*, or *grand fraternity*, under the title of *Our Lady of the Suffrages*, established in favour of the souls in purgatory, approved and confirmed by a bull of pope Clement VIII. in 1594. See *BROTHERS* and *BROTHERS*.

VOL. II. N° 141.

There are nine different sorts of *fraternities*, or confraternities in France, viz. 1. Of Devotion. 2. Of Charity, or Mercy. 3. Of Penitents, under divers names. 4. Of Pilgrimage. 5. Of Merchants to procure the divine favour on their endeavours. 6. Of Officers of Justice. 7. Of the followers of Christ. 8. Of Arts and Trades of divers kinds. And, 9. Of Factions.

Fraternities, in Latin called *confraternitates*, derive their origin from the heathens; as is shown by Polydore Virgil, in his book *De Inventoribus Rerum*. But the good use made of them by the Christians has effectually purged them of any impurities derived from its ill sources.

Namque Confraternitas est. fuit in hanc etiam *fraternitas* of all arts and trades in ancient Rome, and to have prescribed the followers each profession was to perform to the patron or tutelary gods he had assigned them.

FRATERNITY of the holy Trinity. See *TRINITY*.

FRATERNITY is also a title or quality which kings and emperors gave to each other; as also do bishops and monks. We meet with it frequently in authors under the eastern empire, both Greek and Latin: the Greek term is *adelphotes*, *fratellitas*.

FRATERNITY of arms was an alliance, or association in arms, anciently concluded between two knights, who thereby agreed to go together, share their fortune, and mutually assist each other against all the world.

Bertrand du Guesclin and Oliver Clifton twice a *fraternity* of arms in the year 1379, laying their hands on the gospels. Hist. de Bret. tom. i. p. 395.

FRATERNITY of St. Catharine. See *CATHARINE*.

FRATRES Arvalis. See *ARVALES*.

FRATRES conjurati, in our ancient Laws-bols, &c. denote sworn brothers, or companions.

Sometimes they are also so called who were sworn to defend the king against his enemies, leg. W. 1. cap. 59. *Præsumitur, ut omnes liberi homines per fratres conjurati ad monarchiam nostram & regnum nostrum contra inimicos per se ipsos defendendum*.

FRATRES gaudentes. See *Joyful BROTHERS*.

FRATRIAGE, *FRATRIAGIUM*, or *FRERAGE*, the partition among brothers, or coheirs, coming to the same inheritance or succession.

FRATRIAGE is more particularly used for that part of the inheritance which comes to the youngest brothers.

Whatever the cadets, or younger brothers, possess of the father's estate, they possess *ratum fratriagium*, and they are to do homage to the elder brother for it: in regard he is to do homage for the whole to the superior lords.

FRATRICELLI, in *Etymological History*, an enthusiastic sect of FRANCISCANS, which rose in Italy, and particularly in the marquisate of Ancona, about the year 1294.

The word is an Italian diminutive, signifying *fraterechi*, or little brothers; and was here used as a term of derision, as they were most of them apostate monks, whom the Italians call *fratelli*, or *fratellucci*.

For this reason the term *fratelli*, as a nick name, was given to many other sects, as the Catharists, the Waldenses, &c. however different in their opinions and in their conduct. But this denomination applied to the austere part of the Franciscans was considered as honourable. See *FRANCISCANS*.

The founders were P. Mauro, and P. de Fossombroni, who having obtained of pope Celestin V. a permission to live in solitude, after the manner of hermits, and to observe the rule of St. Francis in all its rigour, several idle vagabond monks joined them, who, living after their own fancies, and making all perfection to consist in poverty, were soon condemned by pope Boniface VIII. and his successor, and the inquisitors ordered to proceed against them as heretics; which commission they executed with their usual barbarity. Upon this, retiring into Sicily, Peter John Oliva de Serignan had no sooner published this Comment on the Apocalypse, than they adopted his errors.

They held the Romish church to be Babylon, and proposed to establish another far more perfect one; they maintained, that the rule of St. Francis was the evangelical rule observed by Jesus Christ, and his apostles.

They foretold the reformation of the church, and the restoration of the true gospel of Christ, by the genuine followers of St. Francis, and declared their assent to almost all the doctrines which were published under the name of the abbot Joachim, in the Introduction to the everlasting Gospel, a book published in 1250, and explained by one of the *spiritual* friars whose name was Gerhards. Among other enormities inculcated in this book, it is pretended that St. Francis was the angel mentioned in Rev. xiv. 6. and had promulgated to the world the true and everlasting gospel of God; that the gospel of Christ was to be abrogated in 1260, and to give place to this new and everlasting gospel, which was to be substituted

Altered in its room; and that the ministers of this great reformation were to be humble and bare-footed friars, destitute of all worldly employments.

Some say they even elected a pope of their new church; at least they appointed a general, with superiors, and built monasteries, &c. Beside the opinions of Oliver, they held, that the sacraments of the church were invalid; because those who administered them, had no longer any power or jurisdiction.

They were condemned at length by pope John XXII. in consequence of whose cruelty they regarded him as the true antichrist; but several of them returning into Germany, were sheltered by Lewis, duke of Bavaria, the emperor.

There are authentic records, from which it appears, that not less than two thousand persons were burnt by the inquisition, from the year 1318 to the time of Innocent VI. for their indefatigable attachment to the poverty of St. Francis.

The seven centuries that were again resisted towards the close of the fifteenth century by pope Nicholas V. and his successors. However, notwithstanding all the persecutions which this sect endured, they were not sufficient to extinguish it; but it subsisted until the times of the reformation in Germany, when its remaining veterans adopted the cause, and embraced the doctrine and discipline of Luther. And this has led the papal writers to charge the *fraternalists* with many enormities, some of which are recounted by Mr. Bayle, art. *Fraternalists*.

The *fraternalists* had diverse other denominations: they were called *fraternalists*, according to some, because they lived in community in imitation of the primitive Christians; or rather through the humility of the founder of the Franciscan order, to which the *fraternalists* originally belonged; *dulcini*, from one of their doctors, DIOCRISI, BROUINI, and BERNARDI.

FRATRICIDE, *of frater, brother, and cide, I kill*, the crime of murdering one's brother. See **PARRICIDE**. Cain committed the first *fratricide*; and the empire of Rome began with a *fratricide*.

FRAUD, *fraus*, a secret underhand deceit, or injury, done to any one.

To export or import goods by fraud, or fraudulently, is to do it by indirect ways, in order to avoid the paying of duty, &c. if they be permitted goods; or if they be contraband goods, to avoid the penalties adjudged by the laws.

A fraudulent conveyance of lands or goods to deceive creditors, or to defraud purchasers, is void in law; and the person justifying or putting off such grants as goods, shall forfeit a year's value of the lands, and the full value of the goods and chattels, and likewise be imprisoned.

The several marks of *fraud* in a gift or grant of goods are the following: 1. If be general, without exception of some things of necessity. 2. If the donor still possesses and uses the goods. 3. If the deed be made in secret. 4. If there be a suspicion between the parties. 5. If it be made while the action is depending. When a person is party to a *fraud*, all that follows thereupon will be intended to be done by him, though *fraud* shall not be presumed or adjudged to be so, until it be found by a jury. The statute of *frauds*, 29 Car. II. cap. 3. requires that contracts and agreements, leases, and devises of lands, be in writing. And devises of land, tenes, &c. are deemed fraudulent and void, against creditors, upon bonds or other specialties, 3 and 4 William and Mary, cap. 14. See **CHATEL**.

FRAUS legis, if a person, having no manner of title to a house, procure an affidavit of the service of a declaration in ejectment, and thereupon gets judgment; and, by virtue of a writ of *habeas corpus*, turns the owner out of possession of the house, and seizes and converts the goods therein to his own use: he may be punished as a felon; because he uses the process of the law with a seditious purpose, in *fraudem legis*.

FRAXINELLA, in Botany. See **DITTANY**.

FRAXINUS, in Botany. See **ASH**.

FRAY literally signifies to *fric* as cloth or stuff does by rubbing, or over-much wearing.

Among hunters a *fray* is said to *fray his head*, when he rubs it against a tree, to cause the hairs of his new horns to come off.

FREAM, among Farmers, unable or ploughed land worn out of heath, and laid fallow till it recovers.

FREASE, among Sportsmen, a term used for the noise of a lost in cutting time.

FRICKLES, small, dusky spots, sprinkled on the skin of the face of hands, particularly in persons of the fairer skin, and during the hot seasons, after being exposed to fuliginous vapours, stopped and conglobed in the skin. Vide Turner's Discourse of the Skin, p. 256. They are called in Latin *lentiginis*, from their resemblance

to blance in size and colour to a lentil, by the French they are called *lentilles*, and *brun de Judas*, by the Italians *rustici* and *lentigini*.

Frickles seem to be only the earthy, oily, and saline part, of the sweat, retained in the *plexus* or malices of the skin. While the aqueous liquor, which was their vehicle, is evaporated by the heat of the body, the grosser parts are gradually accumulated, till the malices are full. Some part of this sweat is continually ousting through the cuticle; and, being of a viscid nature, retains the dirt, dust, &c. that fly about the face. This viscid matter on the surface of the *frickles* will stick there, notwithstanding any repeated wiping, which rather condense, and press it into the cavities thereof, than clear it off.

They are found more about the nose, and cheeks of the hands, than any *white else*, because the skin is more stretched there, and consequently the pores more open to receive the dirt, &c.

It follows that there can scarce be any such thing as an *obdurate* remedy, or prevention, of *frickles*. Temporarily one may wash, which shall draw out, and dissipate what matter is already gathered; but the *space* will fill up again in time.

Bullocks gall, mixed with alum, and, after the alum has precipitated, exposed three or four months to the sun in a clovephial, Mont. Hombert shows, is one of the best remedies known for *frickles*. It adds as a balsam, and enters the pores, and dilates and dissolves the conglobum of the *frickles*. Mem. de l'Acad. Royal, des Sciences, an. 1709, p. 473, &c. See the method of preparing and using it under **GALL**.

FREDUM, in Antiquity, a composition made by a criminal to be freed from prosecution, a third part of which was paid into the fiscus or exchequer; and was the price paid to the magistrate for protection against the violence of reclamation. Monast. de Elbert. des Lois, lib. 88. cap. 20. and Robertus's Hist. vol. 1. lib. v. p. 361.

FREE, a term variously used; but generally in opposition to constraint, confined, or necessitated. See **PRAXIS**. Thus, a man is said to be *free*, who is out of prison; and a bird is *free*, when let out of the cage: *free* from pain, i. e. void of pain; we say, a *free* air, a *free* passage, &c.

FREE, in speaking of things endowed with understanding, has a more peculiar relation to the will, and implies its being at full liberty.

The Stoics maintain, that their sage or wise men alone are *free*.

FREE is also used in opposition to slave.

The moment a slave sets foot on English ground, he becomes to some purposes *free*. The harsh usage the ancient Romans could leave their slaves, was their *freedom*.

FREE, *adversus flag*. The frames fly the pump *free* the ship, when it throws out more water than it takes into her; but, on the contrary, when it cannot throw out the water as fast as it takes in, they say the pump cannot *free* her; she bailing or baling out water out of a boat, is called *freering* the boat.

FREE agent. See **AGENT**.

FREE lease, or *franchise lease*, signifies that estate in copyhold lands, which the wife hath after the decease of her husband, for her dower, according to the custom of the manor.

Fitzherbert calls *free lease* a custom, whereby, in certain cities, the wife shall have her husband's whole lands, &c. for her dower.

Thus, at Oulton, in the county of Hereford, the relief of a copyhold tenant is admitted to her *free lease*, i. e. to all her husband's copy hold land, during her life, at the next court after her husband's death.

In the manors of East and West Endbourne, in Berks, if a customary tenant die, the widow shall have a *free lease* in all his copyhold lands, only *duo sibi & capite sibi*: If she commits incontinency, she forfeits her estate; but if she will come into court, suing backwards on a black ram, with her tail in her hand, rehearsing a certain form of words, in the nature of a confession and petition, the steward is bound by the custom to restore to her her *free lease*. The words are these:

Here I am
Riding upon a black ram,
Like a whore as I am;
And for my criminal stomach
I have set my hindum backum,
And for my tail's game
Have done this worldly shame.

Therefore, pray, Mr. Steward, let me have my land again.

The like customs hold also in the manor of Chadsworth, in Berks; that of Tor, in Devonshire; and in some other parts of the West.

FREE-BOOTER, or **FLIBUSTER**, a name given to the pirates, who scour the American seas; particularly such as make war against the Spaniards.

The French call them *flibustiers*, deducing the word from the English *flibber*, or *flibber*; by reason the first adventurers of this kind were the people of St. Domingo, who made their excursions with flibbers, which they had taken from the English. See **Buccanier**.

FREE-BORN, FREE-BORN. In some places three feet, in others more, and in others less, is claimed by way of *free-born*, beyond or without the fence.

Et rium dicitur, quod vocatur broadwode, cum frane bardo ducum fidem, & dimittit per circuitum illius loci. Mon. Ang. 21 part. fol. 241.

FREE-CHURCH, is a chapel founded by the king, and by him exempted from the jurisdiction of the ordinary. See **CHURCH**.

A subject may also be licensed by the king to build such a chapel, and by his charter may exempt it from the visitation of the bishop, &c.

FREE or imperial cities in Germany, are those not subject to any particular prince, but governed, like republics, by their own magistrates.

There were *free cities, libera civitates*, even under the ancient Roman empire: such were those to whom the emperor, by the advice or consent of the senate, gave the privilege of appointing their own magistrates, and governing themselves by their own laws. See **CITY**.

FREE-FIRE. See **FIAT**.

FREE-FIRE. See **FREE** and **FRANK**.

FREE-FIRE. See **MAISON**.

FREE-FIRE. See **PORT**.

FREE-FIRE, is a republic governed by magistrates, elected by the free suffrages of the inhabitants.

FREE-FIRE, a whitish stone, dug up in many parts of England, that works like alabaster; but is more hard and durable, being of excellent use in building, &c.

It is a kind of the *grain stone*, but finer grained, and a smoother stone; and is called *free stone*, from its being of such a constitution as to be cut freely in any direction. This is a species of the *PAVIMENTA* of Hill.

The qualities of the several kinds of *free stone*, in common use in the several parts of Europe, are very different. They all agree in this general property indeed, that they are fitter within the quarry than when they have been some time exposed to the air; but even this general property differs greatly in degree. They have a sort of grey *free stone* in use at Paris, of which we do not seem yet to have met with any quarry in England, though probably enough there are such, which has this property in so eminent a degree, that the expense of working it is in a great measure saved.

This stone lies every where on the south side of the River Seine, and is of a coarse and large grain. It is so soft, when newly taken out of the stone, that they cut it very conveniently with a sort of broad axe, and fashion as many flutes for building in this manner in an hour, as an equal number of our people do in a day or two. Though this stone is as soft as clay when first taken up, it is found to harden so considerably in the air, that it becomes more than equal to our ordinary *free stone*. Our Portland stone, of the finest kind, which is white, and of a close grain, is very fit for hewing or carving, but it will neither resist water nor fire, which is a very singular circumstance in so dense a stone; while the *free stone* of Kent, which is less beautiful to the eye, and is of a greyish colour, and considerably close, though of a larger grain, resists the air and water very well.

The *free stone* of Derbyshire, on the other hand, is so brittle as to be unfit for any fine working, and so coarse and open in its texture that it lets water through; yet it bears the fire extremely well, and is fit for ovens, hearths, &c. Phil. Trans. N° 93.

FREE-FIRE. See **FEUDISTOL**.

FREE-FIRE. See **FEUDISTOL**.

FREE-FIRE, the power of granting or denying licence to any one to hunt in such and such ground.

FREE-FIRE. See **WILL**.

FREEDOM, the quality or state of being *free*. See **FREE**. **FREEDOM** of a city, town, &c. denotes a right or capacity of exercising a certain trade or employment in that city or town corporate, and of being elected to the dignities and offices thereof. It is procured regularly, by having an apprenticeship; but sometimes purchased with money, and sometimes conferred as a favour or compliment.

FREEDOM of the will, a state or faculty of the mind, wherein all the motions of our will are in our power, and we are enabled to determine on this or that; to do good or evil, without any force or constraint from any external cause whatever. See **LIBERTY**, and **NECESSITY**.

FREEDOM of conscience. See **LIBERTY**, and **TOLERATION**. The scholasticus distinguishes two kinds of this *freedom*, viz.

FREEDOM of contradiction, whereby we are at our choice to will, or not to will; to love, or not to love, &c.

Thus, if I give my friend a power to take my horse, that friend has *freedom* of contradiction with respect to the horse; since it is in his own power either to use him, or let him alone.

FREEDOM of contrariety, or of *contrariety*, is that whereby we are at our choice to do good or evil, to be virtuous or vicious.

Thus, if I offer my friend a horse, or a lion, and give him his option of the two, he is said to have a *freedom* of contrariety over the horse and lion.

But the logicians charge this as a faulty or unartful division, in regard one member of the division is contained in the other, as a species in the genus; for whatever is free, in respect of contradiction, is also free in respect of contrariety, though not vice versa: for if it be free for my friend to take the horse, or the lion, it is also free for him to let them both alone; but he may be free to take one of them, without a *freedom* of choosing which to take.

Yet is the distinction of some use; as it intimates, that the will is not always possessed of both kinds of *freedom*, and that the matter or subject of the two is different. The will, though it should be allowed to be free, has not a *freedom* of contrariety; that, any evident truth being proposed to the mind, e. g. that the whole is greater than a part, though we may have a power of not assenting thereto, by diverting our attention to something else, yet we have not a power of dissenting from that proposition, and judging that the whole is not greater than the part.

Hence moralists commonly hold, that with respect to the supreme good, mankind has a *freedom* of contradiction, inasmuch as he may abstain from the love or pursuit thereof; but he has not a *freedom* of contrariety, whereby to hate goodness.

Add, that though the human mind may have a *freedom* of contradiction with respect to all objects, even the supreme good itself; yet the *freedom* of contrariety is restricted to certain particulars, which either are, or appear to be good; the will having such a natural propensity to good, that it cannot desire evil, but under the notion and appearance of good.

FREEDOM of thinking. See **DETERMINATION**.

FREEDOM, **FRANK TENEMENT**, *liberum tenementum*, is land, or tenement, which a man holds in *free tenure*, *freehold*, or for term of life.

Freehold is of two kinds, in *deed*, and in *law*.

The first is the real possession of land or tenement in fee, fee-simple, or for life: the other is the right a man has to such land or tenement before his entry or seizure.

A *freehold* by the common law, cannot commence *tenens*, but it will take effect presently, either in purchase, reversion, or remainder. Whosoever is part of the *freehold* goes to the heart, and things that a *freehold* may not be taken in distress for rent, or in execution, &c. No man shall be distressed of his *freehold*, by Stat. Magna Charta, cap. 29. but by judgment of his peers, or according to the laws of the land: nor shall any distress freeholders to answer for their *freehold*, in anything concerning the same, without the king's writ. *Freehold* estates, of certain value, are required by statutes to qualify jurors, electors of the knights of the shire in parliament, &c. For the method of finding the value of *freehold* estates, see **ANNUITIES** and **LIFE-ANNUITIES**.

Freehold is likewise extended to such offices as a man holds in *fee*, or for life.

Freehold is also sometimes taken to opposition to *villainage*.

Freehold observes, that hind, in the Saxon time, was distinguished into bockland, i. e. holden by book, or writing; and folkland, held without writing.

The former, he says, was held on far better condition, and by the better sort of tenants, as noblemen and gentlemen; being such as we now call *freehold*: the latter was mostly in possession of peasants; being the same with what we now call *the soil of the field*.

In the ancient laws of Scotland, *freeholders* are called *milites*, *knights*. In Reg. Judiciali, it is expressed, that he who holds land upon an execution of a baron's merchant, until he hath satisfied the debt, *tenet ad baron tenementum sibi et agnatis suis*; and the sum of a twelfth penny per acre is the measure of which seems to be, not that such tenants are *freeholders*, but as *freeholders* for the time, till they have received profits to the value of their debt.

FREEDOM, or **FRIZI**, in *Architecture*, that part of the entablature of columns, between the architrave and cornice. See **Tab. Archit.** fig. 24, 25. N° 10, 26, 27, 28. The *friz* is properly a large, flat face, or member, separating the architrave from the cornice.

The ancients called it *mascheras*, *maskers*, because it was usually enriched with figures of animals; and our denomination *frons* has a like origin, being formed of the Latin *frons*, an *embroider*, because it is commonly adorned with sculptures in bas-relief, imitating embroidery.

The *frons* is supposed to be intended to represent the heads of the transverse beams that sustain the roof or covering.

In the *Tuscan* order it is quite plain; in the *Doric*, enriched with triglyphs, or channelled figures, with spaces between them, called *rutings*, which are often plain, and sometimes ornamented; in the *Ionic*, it is sometimes made arched, or *foveled*, in which case it is called by Vitruvius, *foveatus*, q. d. *bellared*; in the *Corinthian*, and *Composite*, it is frequently joined to the architrave, by a little *swarp*, and sometimes to the cornice; and in these richer orders it is usually adorned with sculptures, figures, compartments, historiettes, foliages, festoons, &c. The *frons* of the *Corinthian* order at Palmyra are very richly decorated.

As to the height of the *frons*, it is in general $\frac{1}{2}$ of that of the architrave, but not strictly or exactly. The *Tuscan frons*, Vitruvius makes 30 minutes; Vignola, 35; Palladio, who makes it swelling, gives it but 20; and Scamozzi, 47. The *Doric*, in Vitruvius and Vignola, is 30 or 40 minutes; in Palladio, &c. 45. The *Ionic*, Vitruvius makes $\frac{1}{3}$, adorned with acanthus-leaves, *loma*, &c. and makes it thirty minutes high; Vignola, who also makes it flat, gives it 45 minutes; and Palladio, who makes it convex, or swelling, 27 minutes; and Scamozzi, 32. The *Corinthian*, Vitruvius enriches with acanthus leaves, human figures, &c. and makes its height 37 minutes; Vignola, 45; Palladio, 28; and Scamozzi, 34. Lastly, the *Composite*, which in Vitruvius is set with cartouches, and carved between them, is 52 minutes; Vignola, who makes it like Vitruvius, only gives it 45 minutes; Palladio, who makes it swelling, only 30; and Scamozzi, 32. See the table under *art. COLUMN*. From the variety of enrichments practised on the *frons*, they become variously denominated as

FALCATA, *curved*, or *subulated*, are those whose profile is a curve; the best proportion whereof is, when drawn on the side of an equilateral triangle.

In some, the swelling is only at the top, as in a console; in others at bottom, as in a festoon.

FLEXILE, *swinging*, are those enriched with winds, or imaginary foliages, as the *Corinthian frons* of the frontispiece of Nero, or with natural leaves, either in clusters or garlands; or continued, as in the *Ionic* of the gallery of Apollo in the *Louvre*.

FRETES, *bordered*, are those adorned with bas-reliefs, representing historiettes, fancies, &c. as that of the arch of Titus at Rome.

FRETES, *marina*, are those representing sea-horses, tritons, and other attributes of the sea; or shells, bath, grottos, &c.

FRETES, *typha*, are those whose courses are rusticated, or imbricated, as the *Tuscan frons* of Palladio.

FRETES, *symbolica*, are those adorned with the attributes of religion; as the *Corinthian* of the temple behind the capitol at Rome, whereon are represented the instruments and apparatus of sacrifice.

FRETES of the capital. See *HYPOTRACHELION*.

FRETES, in *Commerce*, a kind of cloth, or stuff. See *FRIZE*.

FREEZING, *negation*, in *Physics*, the fixing of a fluid, or depriving it of its natural mobility, by the action of cold; or it is the act of converting a fluid substance into a firm, coherent, rigid one, called ice.

The Cartesians define *freezing* by the quietude or resting of a fluid body, hindered by cold; which follows naturally enough from their notion of fluidity, where the parts are supposed to be in a continual motion. In effect, one may pretty safely say, with some of these philosophers, that water *freezes*, because, among other reasons, its parts lose their natural motion, and adhere close to each other.

FREEZING, the *physical phenomena* of, are, 1. That water, and all fluids, all alone excepted, dilate in *freezing*; i. e. take more space, and are specifically lighter than before. That the bulk or dimensions of water are increased by *freezing*, is matter of abundant experiment; and here it may be proper to observe the process of nature in this alteration.

A glass vessel, then, B D (*Tab. II. Param. fig. 20.*) full of water to G, being immersed in a vessel of water, mixed with G. R. S. T. V. the water presently rises from K to F; which seems owing to the sudden contraction of the vessel hastily plunged into so cold a medium. Soon after, from the point F it continually descends, condensing, till it arrives at the point G; where, for some time, it seems to remain at rest. But it soon recovers itself,

and begins to expand, rising from G to H; and from thence, soon after, by one violent leap, mounts to I. And here the water in B is immediately seen all thick and cloudy; and in the very instant of this leap, is converted into ice. And, that while the ice is growing harder, and some of the water near the neck of the vessel B is *freezing*, the flux of water is continued above I, towards H, and at length runs out of the vessel.

Mr. Boyle gives us several experiments of vessels made of metals, exceeding thick and strong; in which, when filled with water, close stopped, and exposed to the cold, the water, on *freezing*, coming to be expanded, and not finding either room, or vent, burst the vessels.

A strong barrel of a gun, with water in it, close stopped and *freezed*, was rent the whole length. Huygens, in order to try the force of water which it would expand itself when confined, filled a cannon, the sides of which were an inch thick, with water, and then closed the mouth and touch-hole, in that none could escape. The instrument thus filled was exposed to a strong *freezing air*. In less than twelve hours the water within was *freezed*, and began to dilate itself with such force, that it actually burst the piece in two different places. Mathematicians have calculated the force of the ice upon this occasion; and they say, that such a force would raise a weight of 27,720 pounds; and a small brass vessel, five inches deep, and two in diameter, filled with water, &c. lifted up its lid, which was pressed with a weight of fifty-six pounds. From hence, therefore, we need not be surprised at the effects of ice in destroying the substance of vegetables and trees, and even splitting rocks, when the frost is started to excess.

2. That they lose not only of their specific, but also of their absolute gravity, by *freezing*; so that, when thawed again, they are found considerably lighter than they were before.

3. That *freezen* water is not quite so transparent as when liquid; and that bodies do not perjure so freely through it.

4. That water, when *freezen*, evaporates almost as much as when fluid.

5. That water does not *freeze* in *vacuo*; but necessarily requires the presence and contiguity of the air.

6. That water which has been boiled, *freezes* more readily than that which has not been boiled; and that a slight disturbance of the fluid dispels it to *freeze* more speedily. These two facts have lately been ascertained by the experiments of Dr. Black of Edinburgh. The cause why boiling water accelerates its *freezing*, he supposes to be this; that water which has been boiled has lost the air naturally contained in it, and which, on being exposed to the atmosphere, it begins to attract and absorb. During this process of absorption, which probably continues for a considerable time, a motion is necessarily produced among its particles, which, though imperceptible, may be sufficient to accelerate its congelation.

In unboiled water this disturbing cause does not exist. This account is confirmed by a fact mentioned by Fahrenheit, who discovered, that water, when preserved at rest, may be cooled some degrees below the *freezing* point without *freezing*. Having put water, purged of its air, into small glass globes, and sealed them up, he was surprised to find that the water, exposed to a frosty air, remained much longer unfrozen than he expected. Upon opening some of the globes, and admitting the air, a sudden congelation took place, and a similar production of ice was occasioned in the other globes, by shaking them.

From this discovery, we are able to understand why they boil the water in India, in order to obtain ice; because the utmost intensity of cold they can obtain is not greater than 31° or 32° of Fahrenheit's; but common water may easily be cooled to this degree, provided it be undisturbed, without *freezing*; whereas this cannot happen to boiled water. Phil. Trans. vol. 1st. part I. art. 12.

7. That the water, being covered over with a surface of oil of olives, does not *freeze* so readily as without it; and that not-oil absolutely preserves it under a strong frost, when olive-oil would not.

8. That rectified spirit of wine, muc-oil, and oil of turpentine, seldom *freeze*.

9. That the surface of the water in *freezing*, appears all wrinkled; the rags, or wrinkles, being sometimes in parallel lines, and sometimes like rays, proceeding concentric to the circumference.

FREEZING, the *theory* of, or the methods of accounting for these phenomena, are very numerous. The first principles different authors have gone upon, are either, that some foreign matter is introduced within the pores of the fluid, by whose means it is fixed, its bulk increased, &c.

Or, that some matter naturally contained in the fluid, is now expelled; by the absence whereof the body becomes fixed, &c.

Or, that there is some alteration produced in the texture or form, either of the particles of the fluid itself, or of something contained within it.

To some one of these principles all the systems of *freezing* are reducible.

The Cartesians, who ascribe all to the quietude of the parts of the fluid, before in motion, account for *freezing* from the receding of the ethereal matter out of the pores of the water. The activity of that ether, or subtle matter, they hold to be that which gave the particles of the fluid their motion; consequently, upon the absence of this matter, the fluidity must cease.

Though others of the same sect ascribe *freezing* to a diminution of the usual force and efficacy of the ethereal matter, occasioned by an alteration in the temperature of the air, whereby it is incapacitated for agitating the parts of the fluid as usual.

The Cassidians, and other Corpuscularians, with more probability, ascribe the *freezing* of water to the ingress of a multitude of cold or frigorific particles, which, entering the liquor in swarms, and dispersing themselves every way through it, crowd into the minutest parts of the water, and hinder the wonted agitation of its parts, wedging it up, as it were, into the hard and consistent body of ice. And hence its increase of dimensions, coldness, &c.

This intermixture of a foreign frigorific matter they suppose essential to *congelation*, as that which characterizes and distinguishes it from *coagulation*; the latter being effected indifferently by a hot or cold mixture, but the former only by a cold one.

Of what kind these frigorific particles are, or how they produce their effect, is matter of debate, and has given occasion to various systems.

Hobbes will have them to be common air, which, intruding into the water in congelation, entangles itself with the particles of the fluid, prevents their motion, and produces those numerous bubbles observed in ice; thus expanding its bulk, and rendering it specifically lighter: but this opinion is overruled by Mr. Boyle, who shows, that water will freeze in vessels hermetically sealed, and into which the air can have no ingress; and yet the bubbles will be as numerous herein as in that frozen in the open air. Add, that oil is condensed in *freezing*; consequently, the air cannot there be the cause. Others, of whom there is the greatest number, will have the *freezing* matter to be a salt; arguing, that an excess of cold will render water torpid, but can never congeal it, without salt. They are saline particles, say they, and these dissolved and mixed in a due proportion, that are the chief cause of *freezing*, congelation bearing a near relation to *crystallization*.

This salt they suppose of the nitrous kind, and to be furnished by the air, which is generally allowed to abound in nitre. See AIR, and NITRE.

How the particles of nitre may prevent the fluidity of water, is pretty easily accounted for: these particles are supposed to be so many rigid, pointed spicula, which are easily driven into the lamina, or globules, of the water, and thus becoming variously mingled and entangled therewith, by degrees enfeeble and destroy the motion thereof. The reason this effect only arises in severe winter weather is, that it is then only that the retarding action of the nitrous spicula is more than equal to the power, or principle, whereby the fluid is otherwise kept in motion, or disposed for motion.

This opinion is supported by the known experiment of artificial *freezing*. See FREEZING mixture. Let a quantity of common salt, or salt-petre, be mixed with snow, or ice pulverized, and the mixture dissolved by the fire; upon immersing a tube full of water in the solution, the water, or at least that part of it next the mixture, presently freezes, even in warm air. Whence it is imagined, that the spicula of the salt, by the gravity of the mixture, and of the incumbent air, are driven through the pores of the glass, and mixed with the water; for that it is the salt has the effect, is supposed evident; inasmuch as we know, sufficiently, that the particles of water cannot find their way through the pores of glass. In these artificial *freezing*, whatever part the mixture is applied in, there is presently produced a skin, or lamina, of ice, whether at top, or bottom, or on the sides; because there is always a flock of saline corpuscles sufficient to overpower the corpuscles of fire; but natural congelations are confined to the top of the water, where the salt most abounds.

Against this system the author of the *Nouvelle Conjecture pour expliquer la Nature de la Glace*, objects, that it does not appear, that nitre always enters the composition of ice; but that if it did, it would come short of accounting for some of the principal effects. For how, for instance, should the particles of nitre, by entering

the pores of water, and fixing the parts, oblige the water to dilate, and render it specifically lighter? Naturally they should augment its weight. This difficulty, with some others, evince the necessity of a new theory. That author, therefore, advances the following one, which seems to solve the phenomena in a more easy and simple manner; as not depending on the precarious admission, or extrusion, of any heterogeneous matter.

Water, then, *freezes* in the winter only, because its parts, being then more closely joined together, mutually canbarrel one another, and lose all the motion they had; and the cause of this closer union of the water, is the air; or, more expressly, an alteration in the spring and force of the air.

That there is an infinite number of particles of gross air interspersed among the globules of water, is abundantly evident from experiment; and that each particle of air has the virtue of a spring, is testified: now this author argues, that the small springs of gross air, mixed with the water, have more force in cold winter weather, and unbend themselves more, than at other times; hence these springs, thus unbending themselves on one side, and the external air continuing to press the surface of the water on the other, the particles of water, thus constringed and locked up together, must lose their motion and fluidity, and form a hard consistent body; till a relaxation of the spring of the air, from an increase of heat, reduces the particles to their old dimensions, and leaves room for the globules to flow again.

But this system has its subtle; even the principle on which it stands, may be demonstrated to be false. The spring, or elasticity of the air, is not increased by cold, but diminished. Air expands itself by heat, and condenses by cold; and it is demonstrated in pneumatics that the elastic force of expanded air, is to that of the same air condensed, as its bulk, when rarefied, to its bulk condensed.

It is scarce worth mentioning, that some authors have advanced, to account for the increase of bulk and diminution of specific gravity of frozen water, that the aqueous particles in their natural state were nearly cubes, and so filled that space without the interposition of many pores; but that, by congelation, they are changed from cubes to spheres; whence a necessity of much empty space between them. Cubic particles are certainly much less proper to constitute a fluid, than spherical ones; and spherical particles, less disposed to form a fix, than cubic ones. Thus much the nature of fluidity and firmness easily suggests. For a consistent theory of *freezing*, we must recur either to the frigorific matter of the Corpuscularians, considered under the light and advantages of the Newtonian philosophy; or to the ethereal matter of the Cartesians, under the improvements of M^{rs}. Gassendi, in the *Mémoires de l'Académie Royale des Sciences*, an. 1709.

Each of which we shall here subjoin; and leave the reader to make his choice. For the first: a number of cold saline corpuscles, being introduced into the interstices between the globules of water, may be so near each other, as to be within the sphere of one another's attraction; the consequence of which must be, that they will cohere into one solid or firm body; till heat afterwards, separating them, and putting them into various motions, breaks this union, and separates the particles so far from one another, that they get out of the distance of the attracting force; and into the verge of the repelling force; and then the water resumes its fluid form.

For that cold and *freezing* do arise from some substance of a saline nature, floating in the air, seems probable, hence, that all salts, and more eminently some particular ones, when mixed with snow, or ice, do prodigiously increase the force and effects of cold: add, that all saline bodies do produce a stiffness and rigidity in the parts of those bodies into which they enter.

Microscopical observations upon salts manifest, that the figures of some salts, before they shoot into masses, are thin, double, wedge-like particles, which have abundance of surface with respect to their solidity (the reason why they swim in water when once raised in it, though specifically heavier); these small points of the salt getting into the pores of the water, whereby, also, they are in some measure suspended in the winter-time (when the heat of the sun is not strong enough to dissolve the salts into a fluid, to break their points, or to keep them in perpetual motion), being less disturbed, and more at liberty to approach one another; and, by shooting into crystals of the form above mentioned, do, by their extremities, insinuate themselves into the minutest pores of the water, and, by that means, freeze it into a solid form.

Further, there are many little volumes, or particles, of air, included at several distances, both in the pores of the watery particles, and in the interstices left by the spheri-

tal figures. By the infusation of the saline crystals, the volumes of air are driven out of the watery particles, and many of them uniting, form larger volumes, which thereby have a greater force to expand themselves than when dispersed; and so both enlarge the dimensions, and lessen the specific gravity of the water, thus congealed into ice.

Hence, also, we may conceive how water, impregnated with salts, sulphurs, or earths, which are not easily dissolvable, may form itself into metals, minerals, bitumens, and other fossils; the parts of these mixtures becoming a cement to the particles of water; or, getting into their pores, change them into these different substances.

For the second: as an ethereal matter, or medium, is generally allowed the cause of the motion of fluids; and as the air itself has all its motion from the same principle; it follows that all fluids must remain in a state of rest, or fixity, when this matter loses of its necessary force: of consequence, the air, being less warmed in the winter-time, from the obliquity of the rays of the sun, is denser, and more fixed, in water, than any other season of the year.

But, farther, from divers experiments we have learned, that the air contains a salt, supposed to be of the nature of nitre: this granted, and the density of the air allowed, it follows, that the molecules of this nitre must likewise be brought nearer together, and thickened, by the condensation of the air; as, on the contrary, a rarefaction of the air, and an augmentation of its fluidity, must divide and separate them.

If, now, the same thing happen to all liquors that have imbibed or dissolved any salt: if the warmth of the liquid keep the salt exactly divided; and if the coolness of a cellar, or of ice, give occasion to the molecules of the dissolved salt to approach, run into each other, and shoot into crystals; why should the air, which is allowed a fluid, be exempt from the general law of fluids?

It is true, the nitre, or the air, being grosser in cold weather than hot, must have less velocity; but still the product of its augmented mass, into the velocity remaining, will give it a greater momentum, or quantity of motion; nor is any thing farther required to make this salt act with greater force against the parts of fluids; and, probably, this is the cause of the great evaporation in frosty weather.

This aerial nitre must promote the concretion of liquids; for it is not the air, nor yet the nitre it contains, that gives the motion to fluids; it is the ethereal medium. From a diminution of the force of that, therefore, arises a diminution of the motion of the rest.

Now the ethereal matter being weak enough of itself, in the winter-time, must lose still more of its force by its action against air condensed, and loaded with large molecules of salt: it must, therefore, lose of its force in cold weather, and become less disposed to maintain the motion of fluids. In a word, the air, during frost, may be esteemed like the ice impregnated with salt, wherewith we ice our liquors in summer time. Those liquors, in all probability, freeze, from a diminution of the motion of the ethereal medium, by its acting against the ice and salt together; and the air, for all its scorching heat, is not able to prevent its concretion.

FREEZING MIXTURES, a preparation for the artificial congelation of water and other liquors.

All kinds of salts, whether alkaline or acid, and even all spirits, as those of wines, &c. as also sugar, and saccharum Saturni, mixed with snow, are capable of freezing most fluids; and the same effect is produced, in a very great degree, by a mixture of oil of vitriol, or spirit of nitre, with snow. Thus Mr. Boyle.

M. Homberg observes the same of equal quantities of corrosive sublimate, and sal ammoniac, with four times the quantity of distilled vinegar.

Boerhaave gives us a method of producing artificial frost, without either snow or ice: we must have for this purpose, at any season of the year, the coldest water that can be procured; this is to be mixed with a proper quantity of any salt (sal ammoniac will answer the intention best), at the rate of about three ounces to a quart of water. Another quart of water must be prepared in the same manner with the first; the salt, by being dissolved in each, will make the water much colder than it was before. They are then to be mixed together, and this will make them colder still. Two quarts more of water prepared and mixed in the same manner are to be mixed with these, which will increase the cold to a much higher degree in all. The whole of this operation is to be carried on in a cold cellar; and a glass of common water is then to be placed in the vessel of liquor thus artificially cooled, and it will be turned into ice in the space of twelve hours.

There is a method of making artificial ice by means of snow, without any kind of salt: for this purpose fill a small pewter dish with water, and upon that place a common pewter plate filled, but not heaped, with snow. Bring this simple apparatus near the fire, and stir the snow in the plate: the snow will dissolve, and the ice will be formed on the back of the plate, which was in the dish of water.

Nothing is more commonly known than the method of congealing liquors into ice by an artificial frost, even in the warmest season; but it does not seem to be yet known what are the salts most efficacious of all on this occasion, or, in other words, what salt is capable of producing the greatest degree of artificial cold, or in what manner it may be best used, and what proportion is ought to bear with the powdered ice or snow that is used on the occasion. The common practice is known, but few have enquired so curiously into the whole as to treat a subject seems to deserve.

Mr. Reaumur at length took the whole into consideration, and examined the various degrees of cold by a nice thermometer, which being placed in the liquor to be frozen, showed very exactly the degree of cold by the descent of the spirit.

Salt-petre usually passes for a salt that may be very serviceable in these artificial congelations; but the experiments of this gentleman prove, that this is an erroneous opinion. The most perfectly refined salt-petre employed in the operation sunk the spirit in the thermometer but three degrees and a half below the fixed point.

Of the salt-petre he used, the unrefined makes the spirit sink considerably lower; the cause of which is, that the rough salt-petre contains a large quantity of common, or sea salt; and this being able to cause a greater degree of cold than the salt it is mixed with, extrics itself with it, and carries it to a greater degree of coldness; whereas in the refined salt-petre, this sea salt is thrown out, and consequently the nitre becoming purer, acts only on its own principle, and causes a less degree of cold, such as is its appropriated use.

Two parts of common salt being mixed with three parts of powdered ice in very bad weather, the spirit in the thermometer immediately descended fifteen degrees, which is half a degree lower than it would have descended in the severest cold of the year 1750. Mr. Reaumur after this experimented the salts all round, and tried with great regularity and exactness, what was the degree of cold occasioned by each in a given dose. Among the neutral salts, none produced a greater degree of cold than the common sea salt. Among the alkalies, sal ammoniac, though generally esteemed to be very powerful a one on these occasions, sunk the thermometer only to thirteen degrees. Pot-ashes sunk it just as low as well refined salt-petre. Thus by trials of the several salts, the proper degree of cold producible from each is easily ascertained, and tables may be made of the numbers. After which, in the describing any degree of cold in a particular season, it will be a much better way of expressing it, to say, it was equal to that produced by such or such a salt, than to name it by the degrees of a thermometer.

For the common uses of the table, the ice required is not expected to be very hard, or such as is produced by long continuance of violent cold: it is rather desired to be like snow. Salt-petre, which is no very powerful freezer, is therefore more fit for the purpose than a more potent salt. It is not required that the congelations should be very suddenly made; but its retaining its form as long as may be when made, is a thing of great importance to the dealer in these things; nor is the price of the salts which are to be used for this purpose, a matter of indifference.

If it be desired to have ices very hard and firm, and very suddenly prepared, then sea salt is of all others most to be chosen for the operation. The ices thus made will be very hard, but they will keep only a very little time without running. Pot-ashes afford an ice of about the hardness that is usually required. This form indeed very slowly, but then it will preserve itself a long time. And there is another substance which performs the business very nearly in the same manner with the pot-ashes, and that on the same principle. This is a very clean and simple one, being no other than common wood shavings; but for this purpose the wood, which is burnt, requires to be fresh.

The strong acid spirits of the neutral salts act much more powerfully in these congelations than the salts themselves, or indeed than any simple salt can do. Thus spirit of nitre mixed with twice its quantity of powdered ice, immediately sinks the spirit in the thermometer to nineteen degrees; that is, it produces a cold of four degrees greater than that obtained by means of ice.

sea salt, the most powerful of all the salts in making artificial cold. A much greater degree of cold may be given to this mixture by piling it round with more ice mixed with sea salt. This gives a redoubled cold, and on the trial the thermometer was known to sink to twenty-four degrees; that is, a degree of cold was thus artificially produced, which was to the greatest known natural cold, that of the severest winter in 1769, as twelve to seven, or thereabouts. If this whole matter be covered with a fresh mixture of spirit of nitre and ice, yet a greater degree of cold is produced, and so on; the cold being by this method of fresh additions to be increased almost without bounds: but every addition, it is observed, gives a smaller increase than the former.

It is very remarkable in the acid spirits, that though sea salt is so much more powerful than nitre in substance in creating cold, yet the spirit of nitre is much stronger than that of sea salt; and another not less wonderful phenomenon is, that spirit of wine, a liquor which is little other than a liquid fire, has as powerful an effect in congelations, or very nearly so, as the spirit of nitre itself. What but experiment could have brought people to imagine, that these two so very different liquors could have this property as it were in common?

The mixture of any other matter with powdered ice does not create a new cold by any other means than that of melting the ice it is mixed with. The moment that that melting is therefore the point of time in which the cold is strongest of all, as after that the warmth of the external air, cannot be continually taking off from the new engendered cold. It is plain from hence, that the quicker this melting is performed, the harder the ice must be, or the greater degree of cold. It were much to be wished therefore, that the melting could be instantaneous, as in that case the particles of ice would all act at one and the same time on the matter to be congelated; and in order to this, it is necessary that every particle of ice should have a particle of salt ready to act upon it. This requires that the ice and the salt should be both powdered to a certain fineness. Hence may be deduced a rule, which, though not quite so precise, yet may be sufficiently so for the determining the proper proportion of the salt to be mixed with any determinate quantity of ice. We well know from experiment, how large a quantity of water is necessary to melt a certain quantity of salt of any kind, and repeated experiments might bring the knowledge of the other solution to nearly as great a certainty. It would be well to try the whole carefully with sea salt: and when the proportions of this were known, it would be no difficult matter from these to deduce the proper quantities of other salts, according to their known differences, in regard to the quantities of water necessary to dissolve them.

The several liquid substances which create a cold, in the same manner as the dry salts on being mixed with ice, are much more speedy in their action than the salts; because they immediately and much more intimately come into contact with the particles of the ice, than the salts can. Of this nature are spirit of nitre, spirit of wine, &c. to produce the expected degree of cold, it is always necessary that the ice and the added matter, whatever it be, should both run together and intimately uniting form one clear fluid: it is hence that no new cold is produced with oil, which, though it melts the ice, yet cannot mix itself into a homogeneous liquor with it, but must always remain floating on the surface of the water, produced by the melting of the ice. Mem. Acad. Science. Par. 1734.

Of late there has been a more effectual method of congelating fluids than any yet recited. It has been discovered, that fluids standing in a current of air, grow by this means much colder than before. Fahrenheit had long since informed us, that a pond, which stands quite calm, often acquires a degree of cold much beyond what is sufficient for freezing, and yet no congelation ensues: but if a slight breath of air happens in such a case to brush over the surface of the water, it thins the whole in an instant. However, a phenomenon attends this experiment, which has not yet been explained; for the water, before its congelation, and in its liquid state, sinks the thermometer very low, which shews its excessive degree of coldness; but as soon as it begins to congeal by means of the air, or any other agitation, the thermometer rises to the ordinary freezing point. It has been discovered also, that all substances grow colder by the evaporation of the fluids which they contain, or with which they are mixed. If both these methods, therefore, are practised upon the same body, at the same time, they will increase the cold to almost any degree of intenseness we desire. The most extraordinary instance of artificial freezing that has yet been recorded, is that

of the Russian experiments at Peterburgh, in which quicksilver was congelated.

In December 1759, they had at Peterburgh the coldest weather, and the most intense frost that ever was known, so that De Lisle's thermometer stood at 205 degrees: at that time professor Braun repeated Fahrenheit's experiments, in order to produce artificial cold by means of spirit of nitre combined with pounded ice or snow. Aqua fortis, found by the thermometer to be 204 degrees cold, was poured upon pounded ice, both the ice and aqua fortis being of the same temperature with the air; upon the first pouring, the mercury fell 20 degrees; the spirit was poured off and on again several times, but the mercury in the thermometer fell no lower than 224 degrees, so that no more than 30 degrees of cold could by these means be produced; but as Fahrenheit, Reaumur, and Mulchenbrock, who had repeated the same experiment, could never produce cold greater than 40° below 0 in Fahrenheit's thermometer, which corresponds with 210 in De Lisle's, used by professor Braun, he satisfied himself with having added 20° to the cold formerly known.

However, he determined to vary his experiments; and being under a necessity of using snow instead of ice, which he afterwards found to be much preferable to it, at a time when the snow and aqua fortis were of the same degree of cold with the air, viz. 203°, he immersed the thermometer in snow contained in a glass, and pouring a few drops of the aqua fortis on that part of the snow in which the thermometer was immersed, he observed the mercury to subside to 260; repeating the experiment in the same manner, and pouring on some more aqua fortis, the mercury immediately fell to 340. And, then, immersing the thermometer, before it had lost any of this acquired cold, in another glass filled with snow, the mercury subsided to 470°. Upon taking out the thermometer the mercury was immovable, and continued so in the open air for twelve minutes, and did not recover its fluidity and begin to rise for some minutes after it was carried into a warm room, where the temperature of the air was 125°. He repeated the same experiment, first with the same, and then with another thermometer, with the same success. Professor Braun's thermometer had a spherical bulb, and their scale was divided into 1200 parts, of which 600 were above 0, which denotes the heat of boiling water, and 600 below that heat. He also used another thermometer, the scale of which went no lower than 360° below 0, denoting the heat of boiling water. The mercury soon descended in this thermometer, so that the whole was contained in the bulb; and the immobility of the mercury led him to conjecture, that it might be frozen or become a solid body. But as he had not broken his glasses, he could at that time only form a conjecture. At another time, when the cold was abated, and the thermometer stood at 199°, he repeated the experiment with a little variation: he first put the bulb of the thermometer into a glass of snow, gently pressed down, before he poured on the aqua fortis; he then, in another glass, poured the aqua fortis upon the snow, before he immersed the thermometer in it; and he also put the snow to the aqua fortis, before he put his thermometer in it: but in these several ways he found the event exactly the same; the mercury was immovable; and breaking the bulb of the thermometer, he found the mercury solid, but not wholly so, as the middle part of the sphere was not yet fixed. Mr. Eggenius repeated the same experiment, and the mercury in his thermometer fell with extreme rapidity, almost to the 500th degree; and in breaking the glass from below, he found the quicksilver contained in it absolutely frozen. The quicksilver, thus rendered solid, bore hammering and extension, like other metals; its hardness was like that of lead, though somewhat softer; and, upon striking, it sounded like lead. When the mercury was extended by these strokes, it was easily cut with a penknife, and, in its congelated state, looked like the most polished silver; but in about twelve minutes, after being exposed to the air, which was 197°, it recovered its former fluidity. In this last experiment of Mr. Braun, the mercury descended to 530°, and on the next day, the cold having increased to 112°, it descended to 650. In his following experiments, he invariably found, that the mercury sunk lower, when the whole of it was congelated than if any part of it remained fluid. It then generally descended to 680 and 700, but the bulbs were never in any of his experiments, without cracks: moreover, the mercury, on other occasions, descended to 800, and even to 1500; but, in this last experiment, the bulb was quite broke, so that the globe of mercury, thoroughly frozen, fell out, and by its fall, of about three feet, the ball of mercury became a little compressed. In another experiment, when the mercury descended to 1250°,

1260°, the congealed ball was struck several times with an ax, and became flat like an English half-crown; but receiving some cracks by the blows, it dissolved in about twenty minutes.

Mr. Braun found, that, *ceteris paribus*, the more intense the natural cold was, the more easily and expeditiously did these experiments succeed; though with the nitrous acid poured on snow, mercury may be congealed at any time, when the heat of the atmosphere is not greater than 175° by De Lillie's thermometer: and though the degree of cold necessary to consolidate mercury cannot be precisely ascertained, yet Mr. Braun estimates it to be about 450 degrees in his thermometer. In the process of his observations, Mr. Braun found that double aqua fortis was more effectual than spirit of nitre; but with the simple spirit of nitre, which seldom brings the mercury lower than 300°, mercury may be frozen in the following manner: let six glasses be filled with snow as usual, and the thermometer be put in one of them, and the spirit of nitre be poured upon it; when the mercury will fall no lower in this, remove the thermometer to the second, and so on to the third and fourth, in which fourth immersion the mercury was congealed. Mr. Apina gives the following direction for using the fuming spirit of nitre: take the spirit of nitre, cooled as much as possible, and with it fill half a wine-glass, throwing in as much snow at the same time, and stirring it till it becomes of the consistence of pap; and you thus obtain, almost in an instant, the necessary degree of cold for the congealation of quicksilver. In the experiments above related, distilled quicksilver was generally used; and in some the quicksilver was revived from sublimation.

It is remarked by Mr. Braun, that by the mixture of snow and spirit of nitre, which froze the mercury, he never was able to bring thermometers, filled with the most highly rectified spirit of wine, lower than 300°: so that the cold which will freeze mercury, will not freeze spirit of wine; and therefore spirit thermometers are the most fit to determine the degree of coldness in frigorific mixtures, till we are able to construct solid metallic thermometers with sufficient accuracy. Mr. Braun tried the effects of different fluids in his frigorific mixtures: he always found that Glauber's spirit of nitre and double aqua fortis were the most powerful; and from a number of experiments made when the temperature of the air was between 159 and 155 by his thermometer, he concludes, that spirit of salt poured upon snow, increased the natural cold 30°; spirit of ful ammoniac, 10; oil of vitriol, 35; Glauber's spirit of nitre, 58; aqua fortis, 40; simple spirit of nitre, 30; dulcified spirit of vitriol, 20; Hoffman's anodyne liquor, 32; spirit of hartshorn, 10; spirit of sulphur, 10; spirit of wine rectified, 20; camphorated spirit, 15; French brandy, 12; and several kinds of wine increased the natural cold to 6, 7, or 8 degrees. It appears also, from Mr. Braun's experiments, that both the boiling and freezing of mercury have this in common; that, when it begins to boil, it rises with rapidity, and descends rapidly when it begins to freeze: so that if the mean term of the congealation of mercury be fixed at 650 below 0, and the term of its boiling at 414 above 0, its greatest contraction to its greatest dilatation will be 1064 degrees of Mr. Braun's thermometer, and 1237 of Fahrenheit's, as 212 is the point of boiling water, and 32 the freezing point in Fahrenheit's, which corresponds with 150 under the term of boiling water in Mr. Braun's. Hence every one will see the great alteration of specific gravity in frozen and boiling mercury; as, between one and the other, the tenth part of the volume is lessened. Phil. Trans. vol. ii. part ii. for 1760. art. 64. p. 672. Ibid. vol. iii. part i. art. 31. p. 139. See also an account of some successful experiments for freezing quicksilver at Albany fort, Hudson's bay, in 1775, by Mr. Hutchins, Phil. Trans. vol. lvi. part i. art. to. p. 174. See MERCURY and THERMOMETER.

FREEZING rain, or raining ice, a very uncommon kind of shower, which fell in the West of England, in December, anno 1622. See Phil. Trans. N° 90. This rain, as soon as it touched any thing above ground, as a bough, or the like, immediately settled into ice; and, by multiplying and enlarging the icicles, it broke all down with its weight. The rain that fell on the snow, immediately froze into ice, without sinking in the snow at all.

It made an incredible destruction of trees, beyond any thing in all history. "Had it concluded with some gust of wind," says a gentleman on the spot, "it might have been of terrible consequence." "The spirit of an ash-tree, of just three quarters of a pound, being weighed, the ice thereon weighed sixteen pounds. Some were frightened with the noise in the air; till they discerned it was the clatter of icy

"boughs dashed against each other." Dr. Beale observes, that there was no considerable frost observed on the ground during the whole; whence he concludes, that a frost may be very fierce, and dangerous, on the tops of some hills: while, in other places, it keeps at two, three, or four, feet distance above the ground; rivers, lakes, &c. may wander about, very furiously, in some places, and be remiss in others, not far off. This frost was followed by gentle heats, and a wonderful forwardness of vegetation.

FREEZING of veins. See *Condensing of Wines*.

FREEZING, in Commerce and Manufactures. See *FREEZING*. **FREEZING, in Sea Language**, is a sort of ornamental painting on the upper part of a ship's quarter, stern, or bow. It generally consists of armour, instruments of war, marine emblems, &c.

FREEZELAND, FREEZELAND, or FREEZELAND, bays, in War, the same with *CHIVAL de frise*.

FRIGAROLA, in Libyology, a name given by many to a small river-fish, well known in England by the name of the minnow.

FREGGIA, in Libyology, the name of a long anguilliform fish of the tenia kind, more commonly called CAYACIO.

FREGIT classum. See *CLAUSUM*.

FREIGHT. See *FRAIGHT*.

FEISER, a name used by some for the *STRAWBERRY plant*.

FRENCH, FRANÇOIS, absolutely used, signifies the language of the people of France.

The French, as it now stands, is no original, or mother-language, but a medley of several: there is scarce any language but it has borrowed words, or perhaps phrases, from.

The languages that prevail most, and that are, as it were, the basis thereof, are, 1. The Celtic; whether that were a particular language itself, or whether it were only a dialect of the Gothic, as spoke in the West and North. 2. The Latin, which the Romans carried with them into the Gauls, when they made the conquest thereof. And, 3. The Teutonic, or that dialect of the Teutonic spoke by the Franks, when they passed the Rhine, and established themselves in Gaul.

Of these three languages, in the space of about thirteen hundred years, was the present French formed, such as it is now found. Its progress was very slow; and both the Italian and Spanish were regular languages long before the French.

Palquier observes, it was under Philip de Valois, that the French tongue first began to be polished; and that, in the register of the chamber of accounts of that time, there is a purity seen almost equal to that of the present age.

However, the French was still a very imperfect language till the reign of Francis I. the custom of speaking Latin at the bar, and of writing the public acts and instruments of the courts of justice in that language, had made them overlook the French, their own language. Add, that the preceding ages had been remarkable for their ignorance, which was owing, in good measure, to the long and calamitous wars which France had been engaged in; whence, the French noblesse deemed it a kind of merit, not to know any thing; and the generals regarded little, whether or no they wrote and talked politely, provided they could but fight well.

But Francis I. who was the restorer of learning, and the father of the learned, changed the face of things; and, after his time, Henry Stevens printed his book, *De la Précellence du Langage François*.

The change was become very conspicuous at the end of the sixteenth century; and under Henry IV. Amyot, Coeffeteau, and Malherbe, contributed towards bringing it to its perfection; which the cardinal de Richelieu completed, by the establishment of the French Academy; an assembly, wherein the most distinguished persons of the church, the sword, and the gown, have been members. Nor did the long reign of Louis XIV. contribute a little to the improvement of the language: the personal qualities of that prince, and his taste for the polite arts, and that of the princes of the blood, rendered his court the politest in Europe. Wit and magnificence seemed to vie; and his generals might have disputed with the Greeks, Romans, &c. the glory of writing well, if they could not that of fighting.

From court, the elegance and purity of the language soon spread itself into the provinces; and now there is scarce any body there who does not write and speak good French. One of the characters of the French language is, to be natural and easy. The words are ranged in it much in the same order as the ideas in our minds, in which it differs exceedingly from the Greek and Latin, where the inversion of the natural order of words is reputed a beauty. Indeed the Hebrew surpasses even the French in

in this point, but then it comes short of it in copiousness and variety.

It must be added, however, that as to the analogy of grammar, and the simplicity wherewith the moods of verbs are formed, the English has the advantage, not only over the French, but over all the known languages in the world; but then the turns, the expressions, and the idioms, of the English, are sometimes so quaint, and extraordinary, that it loses a good deal of the advantage which its grammatical simplicity gives it over the rest.

The French has but few compound words; whereas it differs widely from the Greek, High Dutch, and English. This the French authors own a great disadvantage in their language; the Greek and Dutch deriving a great part of their force and energy from the composition of words, and frequently expressing what in one sounding word, which the French cannot express but by a periphrasis. The diminutives in the French are as few as the compounds; the greatest part of those remaining in use having lost their diminutive signification; but what distinguishes the French most are its justness, purity, accuracy, and flexibility.

French is the most universal and extensive language in Europe. The policy of states and courts has rendered it necessary for the ministers of princes, and their officers, &c. and the taste of arts and sciences has had the same effect, with regard to the learned.

In Germany, and elsewhere, the princesses and persons of distinction value themselves on understanding French; and in several courts of Europe, French is almost as much known as the language of the country; though the court of Vienna is an exception from this rule. French is there very little used; the emperor Leopold could not bear to hear it spoke in his court; the Latin and Italian are there cultivated instead of it. This extensiveness of the French language is no modern advantage; William the Conqueror gave laws to England in the French language; and the ancient customs of most of the provinces of the Netherlands are wrote in the same.

Lastly, the French is the same language every where; not only in all the provinces of France, but in all places where it is spoken, out of France.

For a critical acquaintance with what regards the French tongue, see the Remarques of M. Vaugelas; and the Observations M. Cornet has made on those remarks; the Remarques of F. Bouhours; and the Doubts of a Bas-Breton gentleman, by the same father; the Conversations of Ariste and Eugene; the Observations of M. Menage, and his Etymologies, with those of M. Huet; F. Butler's French Grammar; and that of the abbé Regnier. Add, the two Dicoctiques of the abbé de Dangeau; one on the vowels, and the other on the consonants, and many later works.

FRENCH grass, a name given by our farmers to a plant raised for the food of cattle, and more properly called **SAINT-FIN**. It had its name *French grass*, from its coming originally to us from France, and from its use in serving both fresh and dried for the food of cattle; the common clover is called *grass* also by the farmers, though neither this nor the other are properly grasses. Some of our farmers also call it everlasting grass, from its long continuance, a strong crop often yielding a plentiful annual produce for forty years without any renewing.

FRENCH Man. See **FRAINGENIA**, and **ENGLISHERY**.

FRENCH Masquer, Mince, O'dor, Pasquade, Pez, Silk, Whiggle. See the **substantives**.

FRENCH Wines, duty on. See **DUTY**.

FRENK. See **FRAENG**.

FRENUM, or **FRNUM.** See **FRENUM**.

FRENZY, and **FRENKIC.** See **FIRENRY**, and **PHRENETIC**.

FRESCO, in the *Arts*, a kind of painting performed on fresh plaster, or on a wall laid with mortar not yet dry; and with water-colours.

This sort of painting has a great advantage; by its incorporating with the mortar, and drying along with it, it is rendered extremely durable; and never fails or falls, but along with it. The Italians, from whom we borrow the term, call it *frisco*, because it is frequently used for walls, alcoves, and other buildings, in the open air. Vitruvius, lib. vii. cap. 4. calls it *opus testaceum*. Painting in *frisco* is very ancient, having been practised in the earliest ages of Greece and Rome. It is chiefly performed on walls and vaults, newly plastered with lime and sand; but the plaster is only to be laid, in proportion as the painting goes on; no more being to be done at once, than the painter can dispatch in a day, while it dries.

Before he begins to paint, a cartoon or design is usually made on paper, to be calked, and transferred to the wall, about half an hour after the plaster is applied.

The ancients painted on stucco; and we may remark in Vitruvius what infinite care they took in making the incrustation or plaiting of their buildings to render them beautiful and lasting; though the modern painters find a plaster made of lime and sand preferable to it; both as it does not dry so hastily, and absorbing a little brownish, it is fitter to lay colours on, than a ground so white as stucco.

In this kind of painting, all the compound and artificial colours, and almost all the minerals, see **set aside**, and scarce any thing is used but earths; which are capable of preserving their colour, defending it from the burning of the lime, and resisting its salt, which Vitruvius calls its *biternefs*.

For the work to come out in all its beauty, the colours must be laid on quick, while the plaster is yet moist; nor should they ever be retouched; dry, with colours mixed up with the white of an egg, or size, or gum, as some workmen do; because such colours grow blackish; nor do any preserve themselves, but only such as were laid on hastily at first.

The colours used, are white made of lime slackened long before, and white marble dust; ocher, both red and yellow; verditer; lapis lazuli; smalt; black chalk, &c. All which are only ground, and worked up with water; and most of them grow brighter and brighter, as the *frisco* dries.

The brushes and pencils for this work ought to be long and soft, otherwise they will rake and raise the painting. The colours should be full, and flowing from the brush; and the design perfect; for, in this work, you cannot alter or add upon any colour.

FRESH diffision, in *Law*, (*frisco diffision*, from the French *frain*; i. e. *recom*, & *diffusion*, *viz. persiffler* *giare*) signifies that *diffision* which a man might formerly seek to defeat of himself, and by his own power, without resorting to the king or the law; as where it was not above fifteen days old, or some other short continuance. Britton, cap. 5. Of this Bracton writes at large, concluding it to be arbitrary. Lib. iv. cap. 5.

FRESH five, is that which was levied within a year past. Wellm. 2. cap. 45. See **FINN**.

FRESH force, frisco fortis, in *Law*, denotes a force done within 40 days.

If a man be dispossessed of lands or tenements, within any city or borough; or deposed from them after the death of his ancestor, to whom he is heir; or after the death of his tenant for life, or in tail, he may, within forty days after his title accrued, have his remedy by an assize, or bill of *fresh force*.

FRESH the hauls, on board a Ship. See **HAUL**.

FRESH Shot, in the *Seashore*, signifies the falling down of any great river, into the sea; by means whereof the sea hath fresh water a good way from the mouth of the river. As this is more or less, they call it a *great*, or *small fresh shot*.

FRESH Spelt, in the *Seashore*, a fresh gang, to relieve the rowers in the long boat.

FRESH Suit, reus infortis, in *Law*, is such a present and active prosecution of an offender, where a robbery is committed, as never ceases, from the time of the offence committed, or discovered, till he be apprehended.

The benefit of such pursuit of a felon is, that the party pursuing shall have his goods restored to him; whereas otherwise they are the king's.

Though the party robbed doth not apprehend the thief immediately, but some time after the robbery, provided he used his utmost endeavours to take him; or though he happens to be apprehended by some other person, yet it shall be adjudged *fresh pursuit*.

Fresh suit is either within the view, or without. Manwood says, that upon *fresh suit* within the view, trespasses in the forest may be attached by the officers pursuing them, though without the limits of the forest. *Fresh suit* may continue for seven years. See **HUE and CRY**.

FRESH Water, is that not incitrated, or impregnated with salt, or saline particles, enough to be discovered by the sense.

Such generally is that of springs, rains, wells, lakes, &c. Dr. Lister is of opinion, that the natural and original kind of water is to be salt; the *freshness* he supposes to be accidental, and to be owing to the vapours of plants, and the breath of animals therein; and to the exhalations raised by the sun.

Others will have all water originally *fresh*, and take its saltness to be accidental; to account for which, a great number of hypotheses have been framed.

The saltness of water is a foreign, and in most cases a harmful quality. It renders it not only nauseous to the taste,

taste, but greatly prejudicial to the body; and it is generally agreed, that those waters, *cattis paribus*, are best, not only for drinking, but also for economical uses, as washing, boiling, and brewing, which are the freest from saltness.

Hence various methods have been contrived for examining the *freshness* of waters, and for dulcifying or making salt water *fresh*.

Mr. Boyle gives us a method of examining the *freshness* of water, by means of a precipitate, which calls down any saline particles before floating therein.

Into one thousand grains of distilled water he puts one grain of salt; and into the solution lets fall a few drops of a strong well filtrated solution of a well refined silver, dissolved in clear aqua fortis; upon which there immediately appears a whitish cloud, which, though but slowly, descends to the bottom, and there settles in a white precipitate, in which is the saline matter of the fluid.

This method, if it were required, would examine water to a greater nicety, than that here specified. It has discovered salt in water where there was but one grain of salt in two thousand, nay in three thousand times the weight of water.

The experiment was tried before the Royal Society, in 1692, by Sir Hans Sloane; where it was likewise found that a drop or two, even of spirit of salt, mixed with common water would be discovered by the same method. Phil. Trans. abr. vol. ii. p. 208.

Dr. Hook, in the same year, read a lecture before the Royal Society, on a method of his own, for discovering the smallest quantity of salt contained in water, on a principle of hydrostatics. The operation was performed by means of a large pipe of glass, of the shape of a bottle; the ball thereof was three inches in diameter, and the neck $\frac{1}{2}$ of an inch. This being poised, with red lead put in it, so to make it very little heavier than *fresh* water; and then suspended by the small stem, which was graduated, to the end of a nice beam of a balance; and the degree or division of the neck, contiguous to the surface of the water, noted; upon infusing a quantity of salt, only equal to the two thousandth part of the weight of the water, the neck of the pipe sunk near half an inch lower in the water. Phil. Trans. abr. vol. ii. p. 304.

The dulcifying, or making of salt water *fresh*, is a secret, that has been long sought with great attention. For an account of the principal attempts that have been made with this view, see *Salt-Water*.

FRESH Wind signifies strong, but not violent; hence when the gale increases, it is said to freshen.

FRESHES, in *Sea-language*, denote the impetuosity of an ebb-tide, increased by heavy rains, and flowing out into the sea, often discolouring it to a considerable distance, and forming a line that separates the two colours, and which may be distinctly perceived for a great length along the coast.

FRET, or *FRETT*, in *Architecture*, a kind of knot, or ornament, consisting of two lilia, or fillets, variously interlaced, or woven, and running at parallel distances, equal to their breadth. See *Tab. Archit. fig. 34*.

A necessary condition of these *frets* is, that every return and interfection be at right angles. This is so indispensable, that they have no beauty without it, but become perfectly Gothic.

Sometimes the *fret* consists but of a single fillet, which, if well managed, may be made to fill its space exceedingly well.

The ancients made great use of these *frets*; the places they were chiefly applied on were even, flat members, or parts of building; as the faces of the corona, and eaves of cornices; under the roofs, soffits, &c. on the plinths of bases, &c.

The appellation was occasioned hence, that the French word *frette* literally signified the timber-work of a roof, which consists chiefly of beams, rafters, &c. laid across each other, such as it were, *fretted*.

FRET, in *Music*, is used for the stops used on some instruments, especially bass viols and lutes; it consists of strings tied round the neck of the instrument, at certain distances, within which such and such notes are to be found. These strings or *frets* are sometimes, yet seldom, put on the bass violin for learners, and taken off again when they can find the notes without them. On lutes and viols they always remain.

FRET, or *FRETTE*, in *Heraldry*, is a bearing consisting of six bars, crossed, and interlaced, *fretwise*; as in *Tab. Herald. fig. 39*.

Goullim derives the word from the French *rets*, not; but the reader will easily furnish himself with a better etymology from the word *fret*, in architecture. He bears diamond a *fret* topaz; the coat armour formerly of the lord Maltravers, and now quartered by the duke

of Norfolk. When it consists of more than six pieces, the number must be specified.

Some call this the *true lovers knot*; others *Herringman's knot*, because it is their arms; and *node firmis*, the motto. Gibbon is for calling it *heraldicum nudus amictus illi*.

FRETTY, in *Mineralogy*, a term used by our miners to express the worn side of the banks of the rivers in mountain-countries, where they search for the *HYDRO* flosses, or grews, washed down from the hills, in order from thence to trace out the running of the flood up to the mine. Phil. Transact. N^o 69.

FRETTY, or *FRETTE*, in *Heraldry*, is where there are divers bars laid across each other.

Fretty is of six, eight, or more pieces. *Azure, fretty* of eight pieces, or, the coat of the lord Willoughby.

Columbiere observes, that *fretty*, absolutely used, without any addition, is supposed to be of six pieces; that is, so many bars, or pieces, crossing each other, which, therefore, need not be expressed; but if there be more, as much must be mentioned. And yet Goullim has *azure, fretty* of six; argent; the coat of the ancient lords Ellingham, of Suffolk.

FREUM, *freight*, or *stright*, in *Geography*. See *STRAIGHT*.

FRET-work, an enrichment of *frets*, or a piece adorned with something in manner thereof. See *FRET*.

Fret-work is sometimes used, among us, to fill up and enrich flat, empty spaces; but it is principally practised in roofs, which are *fretted* over with plaster-work.

The Italians, also, apply it to the paintings of chimneys, with great figures; a cheap piece of impudence, and as durable almost within doors, as harder matters in the weather.

FRIABLE is applied to bodies to denote them tender and brittle, easily crumbled or reduced to powder between the fingers; their force of cohesion being such as easily exposes them to such solution. Such are pumice, and all calcined flosses, burnt alum, &c.

Friability is supposed to arise hence, that the body consists wholly of dry parts, irregularly combined, and which are readily separated, as having nothing unctuous or glutinous to bind them together.

FRIAR, or *FRIER*, by the Latins called *frater*, the Italians *fra*, and the French *frere*, that is, *brother*, is a term common to the monks of all orders; founded on this, that there is a kind of fraternity, or brotherhood, presumed between the several religious persons of the same convent or monastery.

The kinds of *friars* are very numerous: *AUGUSTINE* *friars*; *DOMINICAN*, or black, or preaching, *friars*; *FRANCISCAN*, or grey, or begging, *friars*; and *CARMELITES*, or white *friars*.

FRIAR, in a more peculiar sense, is restrained to such monks as are not priests; for those in orders are usually dignified with the appellation of *FATHERS*.

FRIARS, or *FRIERS obervants*, *fratres obervantes*, were a branch of the Franciscans; thus called, because not combined together in any cloyster, convent, or corporation, as the conventuals are, but only agreed among themselves to observe the rules of their order, and that more strictly than the conventuals did, from whom they separated themselves out of a singularity of zeal, living in certain places of their own chusing.

FRIAR's cowl, in *Bacon*. See *WAKE Robin*.

FRIARY of the holy Trinity. See *TRINITY*.

FRIBURGH, *FRIEDBURGH*, or *FRIBURG*, among our Anglo-Saxon ancestors, denoted the same as *FRANK*; pledge did after the time of the Conquest.

Fraternitas est quodam iunctura & maxima securitas, per quam omnes statu firmissime sustentantur, vix, ut unusquisque stabilitur sit sub plurimorum securitate, quam Angli vocant freo-borghes: sed tamen Eboracensis dicitur eandem tennennantale, quod fons Latine decem hominum numerum. I.L. Edw. II. ap. Lamb.

Every man in this kingdom was anciently associated in some decennary, or company of ten families, who were pledged, or bound, for each other, to keep the peace, and observe the law. See *TITHING*. If any offence was done by one, the other nine were to answer it; that is, if the criminal fled from justice, they had thirty days allowed to apprehend him: if he was not taken in that time, he who was the *friurburgh*, i.e. the principal pledge of the ten, should take two of his own number, and the chief pledges of three neighbouring *friurburghs*, with two others out of each of the said *friurburghs*, who were to purge themselves, and their *friurburgh*, of the forfeiture and flight of the criminal. If they could not do this, the principal pledge, with the other eight, were to make satisfaction.

Great men were not combined in any ordinary decennary, or dozen, as being deemed a sufficient assurance for themselves and their menial servants.

FRICASSEE, a dish, or meats, hastily dressed in a frying-pail, and seasoned with butter, oil, or the like.

The word is French, formed of the Latin *fricare*, *frying*. Others will have *fricasso* formed in imitation of noise made by butter, or other fat, when melted in the pan.

We lay a *fricasso* of pullets, of rabbits, of tence, of tripe, of frogs, of eggs, of peas, &c.

FRICULUM, of *fricula*, in *Pharmacy*, a name given to such medicines as are intended to be rubbed into the several parts of the body. The ancients had three kinds of *fricula*, the dry, the soft, and the liquid; the first was used in the way of fumigation, the second was bound on the part with cloths, and the last was used by way of embrocation.

FRICITION, the act of rubbing or grating the surface of one body against that of another, called also *attrition*. The phenomena arising upon the *fricition* of divers bodies, under different circumstances, are very numerous and considerable.

Mr. Hawtke gives us a number of experiments of this kind; particularly of the *attrition*, or *fricition* of glass, under various circumstances, the result of which was, that it yielded light, and became electrical.

All bodies by *fricition* are brought to conceive heat; many of them to emit light; particularly a cat's back, sugar, beaten sulphur, mercury, sea-water, gold, copper, &c. but, above all, diamonds, which, when briskly rubbed against glass, gold, or the like, yield a light equal to that of a live coal when blown by the bellows. See **ELECTRICITY AND ELECTRICITY**.

FRICITION, in *Mechanics*, denotes the resistance a moving body meets with from the surface on which it moves.

Fricition arises from the roughness or asperity of the surface of the body moved on, and that of the body moving: for such surfaces confining alternately of eminences and cavities, either the concavities of the one must be raised over those of the other, or they must be both broken and worn off, but neither can happen without motion, nor can motion be produced without a force impeded. Hence, the force applied to move the body is either wholly, or partly, spent on this effect; and consequently there arises a resistance, or *fricition*, which will be greater, *ceteris paribus*, as the eminences are the greater, and the substance the harder: and as the body, by continual *fricition*, becomes more and more polished, the *fricition* diminishes.

Hence it follows, that the surfaces of the parts of machines that touch each other should be as smooth and polished as possible. However it is found by experience, that the flat surfaces of metals, or other bodies, may be so far polished as to increase *fricition*; because the attraction of cohesion becomes sensible, as we bring the surfaces of bodies nearer and nearer to contact. But as no body can be so much polished, as quite to take away all inequality; witness those numerous ridges discovered by the microscope on the smoothest surfaces; hence arises the necessity of anointing the parts that touch with oil, or some other fatty matter.

FRICITION, *laws of*. 1. As the weight of a body moving on another is increased, so is the *fricition*.

This we see experimentally in a balance, which, when only charged with a small weight, easily turns; but with a greater, a greater force is required.

Hence, if the line of direction of a moving body be oblique to the surface moved on, the *fricition* is the greater; this having the same effect as an increase of weight.

And hence, again, as a perpendicular stroke or impression is to an oblique one, as the whole line to the line of the angle of incidence; and the line of a greater angle is greater, and that of a lesser less; the *fricition* is the greater, as the line of direction approaches nearer to a perpendicular.

This is easily observable, and especially in the teeth of wheels, which are frequently broke on this very account. The *fricition*, therefore, is taken away, if the line of direction of the moving body be parallel to the surface.

2. The *fricition* is less in a body that rolls than it would be were the same body to slide, as is easily demonstrated. For suppose a dented ruler, A B, *Tab. Mechanicæ*, fig. 12, and suppose a wheel D E to move along with it, with its teeth perpendicular to the circumference; if now the body were to slide, the tooth F, when it touched the ruler, would describe a right line on the surface thereof, and, as the tooth of the ruler H resists the same, it could not proceed without removing or breaking either the tooth H, or that F. And the same will hold in the sliding of any rough surface upon another, where all the *fricition* will take place that can any way arise from the roughness of the surface. But if the wheel E D roll

along the ruler, then the tooth H will no longer resist its motion, only as it is to be hoisted out of the cavity F over the eminence of the tooth H; and the same holds in the rubbing of any rough body over the surface of another.

Hence, in machines, left the *fricition* should employ a great part of the power, care is to be taken, that no part of the machine slide along another, if it can be avoided; but rather that they roll, or turn upon each other. With this view it may be proper to lay the axes of cylinders, not, as it is usually done, in a groove, or concave matrix, but between little wheels, ABCD, fig. 13, moveable on their respective axes: for, by this contrivance, the *fricition* is transferred from the circumference of those wheels to their pivots; and the *fricition* may be still diminished further, by making the axes of those wheels rest upon other *fricition*-wheels that turn round with them. This was long ago recommended by P. Calatus; and experience confirms, that we have much power by it. Hence also it is, that a pulley moveable on its axis lifts less than if it were fixed. And the same may be observed of the wheels of coaches, and other carriages.

From these principles, with a little farther help from the higher geometry, Olaus Roemer determined the figure of the teeth of wheels, that should make the least resistance possible, and which should be epicycloidal. And the same was afterwards demonstrated by De la Hire; though, which is much to be lamented, the thing is not yet taken into practice.

Hence, in sawing-mills, the sides of the wooden rectangle the saws are fitted into, should be furnished with rotule, or little wheels, which would greatly lessen the *fricition*; and the like in other cases.

FRICITION, calculation of the quantity of. The *fricition* is a point of the utmost importance in machines; and by all means to be considered, in calculating the force thereof; yet it is generally overlooked in such calculations; but this is principally because its precise value is not known. It is not yet reduced to certain and infallible rules: since it depends upon the structure of bodies, the form of their prominent parts and cavities, and upon their rigidity, their elasticity, their coherence, and other circumstances. The common method is, barely to compute the advantage, which a moving power has from the machine; either on account of its distance from a fixed point; or of the direction in which it acts. And in all the demonstrations it is supposed, that the surfaces of bodies are perfectly smooth and polished. Indeed the engineers expect, that in the practice they should lose part of the advantage of their force, by the *fricition*: but how much, it is supposed, nothing but the practice can determine. M. Amontons, indeed, has made an attempt to settle, by experiment, a foundation for the precise calculation of the quantity of *fricition*; and Mr. Parent has confirmed it, from reasoning and geometry: but their theory, however warranted, is not generally and fully received.

M. Amontons's principle is, that the *fricition* of two bodies depends on the weight, or force, wherewith they bear on each other; and only increases as the bodies are more strongly pressed, or applied, against each other, or are charged with a greater weight; and that it is a vulgar error, that the quantity of *fricition* has any dependence on the bigness of the surfaces rubbed against each other; or that the *fricition* increases as the surfaces do. Thus if a piece of wood four inches wide and one inch thick be ground, and thereby made exactly fit to the surface of another fixed piece of the same wood, it will require the same weight to draw it along on the same, whether it be laid on its broad or narrow side: for, though on the broad side there be four times the number of touching particles (*ceteris paribus*), yet each particle is pressed with but $\frac{1}{4}$ of the weight bearing on those of the narrow side; and since four times the number multiplied by $\frac{1}{4}$ of the weight is equal to 1 of the number multiplied by four times the weight, it is plain that the effect, that is, the resistance, is equal in both cases, and therefore requires the same force to overcome it.

Upon the first proposal of this paradox, M. de la Hire had recourse to experiments; which succeeded much in favour of the new system. He laid several pieces of tough wood on a rough table; their sizes were unequal; but he laid weights on them, so as to render them all equally heavy; and he found, that the same precise force, or weight, applied to them by a little pulley was required to put each in motion, notwithstanding all the inequality of the surfaces. The experiment succeeded in the same manner in pieces of marble, laid on a marble table. Upon this M. de la Hire betook himself to the rationale of the thing; and he has given us a physical solution of the effect. And M. Amontons has settled a calculus of the value of *fricition*;

friction; and the loss sustained thereby in machines, on the foundation of the new principle.

In wood, iron, lead, and brass, which are the principal materials used in machines, he finds the resistance, caused by *friction*, to be nearly the same, when those materials are anointed with oil, or other fatty matter; (but this fact has been disputed by Muehlenbroeck, and experiments urged in proof of the contrary; and this resistance, independent of the quantity of surface, he makes to be nearly equal to a third part of the force wherewith the bodies are pressed against each other. Others have observed, that, if the surfaces be hard and well polished, the *friction* will be less than a third part of the weight; but if the parts be soft or rugged, it will be much greater. Let a very smooth cylinder of wood AB, Tab. III. *Mechanics*, fig. 44. be laid on two well-polished and oiled or greased supports C and D, and be charged with the weight of two pounds in the two equal balls G, H; it will require an additional weight γ equal to about a third part of the two pounds) to give motion to, or overcome the *friction* of the said cylinder. But this additional weight, as it causes a greater pressure of the cylinder, will increase the *friction*, and require the addition of another weight γ , equal to a third part of its own; for the same reason the weight γ , will require another $\frac{1}{3}$ a third part of two pounds and so on *ad infinitum*. Therefore if the *friction* is precisely equal to a third of the weight, the first weight, with all the additional ones viz. 2, $\frac{2}{3}$, $\frac{4}{9}$, &c. will be a series of numbers in geometrical progression decreasing; and the sum of all these terms, omitting the first, i. e. the sum of the infinite number of additional weights $\frac{2}{3} + \frac{4}{9} + \frac{8}{27} + \dots$ &c. is equal to one pound: so that if the weight of the cylinder be inconsiderable, the way to overcome the *friction* will be to double the power G or H at once.

But if the cylinder moved on the two small gudgeons E and F, or on a small axis, the *friction* would be abated in the same proportion as the diameter of these gudgeons is less than the diameter of the cylinder, because in this case the parts on which the cylinder moves and rolls will have less velocity than the power which moves it in the same proportion. See *WHEEL-CARRIAGE*.

The above recited hypothesis of M. Amontons has been adopted and confirmed by M. Camus, Desaguliers and others. In order to estimate the quantity of *friction* in any engine, begin at the power and consider the velocity and the weight at the first rubbing part, and determine the quantity of *friction* by the foregoing principles; then proceed to the next rubbing part, finding the *friction* there, &c. Mr. Emerson, in his *Principles of Mechanics*, deduces from experiments the following remarks relating to the quantity of *frictions* when a cubic piece of soft wood of eight pounds weight, moves upon a smooth plane of soft wood, at the rate of three feet per second, its *friction* is about one third of the weight; but if it be rough, the *friction* is little less than half the weight: on the same supposition, when both the pieces of wood are very smooth, the *friction* is about one fourth of the weight; the *friction* of soft wood on hard, or of hard wood upon soft, is one fifth or one half of the weight; of hard wood upon hard wood, one seventh or one eighth; of polished steel moving on steel or pewter one fourth; moving on copper or lead, one fifth of the weight. He observes in general, that metals of the same sort have more *friction* than those of different sorts; that lead makes much resistance; that iron or steel running in brass makes the least *friction* of any; and that metals oiled make the *friction* less than when polished, and twice as little as when unpolished. Desaguliers observes that, in Mons. Camus's experiments on small models of sledges in actual motion, there are more cases wherein the *friction* is less than where it is more than one third of the weight. See a table, exhibiting the *friction* between various substances, formed from his experiments in *Des. Exp. Phil.* vol. i. p. 193. &c.

Beside the *friction*, the magnitude whereof determines that of the *friction*, there is another circumstance to be considered; viz. the velocity. The *friction* is the greater, and the more difficult to surmount, as the parts are rubbed against each other with the greater swiftness; so that this velocity must be compared with that of the power necessary to move the machine, and overcome the *friction*. If the velocity of the power be double that of the parts rubbed, it acquires, by that means, an advantage that makes it double; or, which amounts to the same, it diminishes the contrary force of *friction* by one half; and reduces it to a sixth part of the weight or pressure. But this velocity M. Amontons only considers as a circumstance that augments or diminishes the effect of the pressure, i. e. the difficulty of the motion; so that the *friction* still follows the proportion of the weight. Only, we are hereby directed to dispose the parts of machines that rub against each other, in such manner, as that they may have

the least velocity possible: and thus the diameter of the axis of a wheel should be as small as possible, with regard to that of the wheel; in that the lesser the axis, the slower will be the motion of the surfaces rubbing against each other; since the velocity of a circular motion always goes diminishing from the circumference to the centre; and, for the same reason, the teeth of dented wheels should be as small and as thin as possible; for a tooth catching on a notch, &c. rubs one of its sides against a surface equal to its own; and is to disengage itself, in a certain time, by pulling over a space equal to the surface; consequently, the lesser the surface, the less space it has to move; the smallness of the surface diminishing the resistance of the *friction*; not as it is a less surface that rubs, but as there is a less space to move. The following general proposition may be deduced from the preceding remarks viz. That the resistances arising from *friction* are to one another in a ratio compounded of the pressures of the rubbing parts, and the times or velocities of their motions.

But, notwithstanding all the confirmations and illustrations of this theory of *friction*, the public, or even the academy itself where it was proposed, could not be brought fully to acquiesce in it. Muehlenbroeck and the abbé Nollet have concluded from experiments that the *friction* of bodies depends on the quantity of their surface as well as their weight. *Introd. ad Phil. Nat.* vol. i. c. 9. and *Lect. Phys. Exp.* tom. i. p. 241. There is scarce any subject of experiment, with regard to which different persons have formed such various conclusions, so that the nature and laws of *friction* are not yet sufficiently clear and decisive. It is granted, that the pressure has a great effect, and is, in many cases, the only thing to be considered in *frictions*: but it will be hard to persuade us absolutely to exclude the consideration of the surface. In effect, the contrary seems capable of metaphysical demonstration.

If two bodies, with plain surfaces, supposed infinitely hard, and polished, be moved along each other, the *friction* will be none or infinitely small; but if, in lieu of such supposition, which has no place in nature, we suppose two bodies, with rough uneven surfaces, the difficulty of moving one of them on the other must either arise from this; that the first is to be raised, in order to disengage the parts caught or locked in the second; or that the parts must be broken, and worn off; or both. In the first case, the difficulty of raising one of the bodies makes that of the motion; and of consequence the *friction* arises wholly from the weight, or pressure; and the surface has nothing to do in it.

In the second case, the magnitude of the surface would be all; were it possible this second case could be absolutely abstracted from the first, i. e. could the parts of one body be rubbed and worn against those of the other, without raising one of them; it being visible, that a greater number of parts to be broken would make a greater resistance than a less; but as in practice we never rub, or grind, without raising the body, the resistance arising from the greatness of the surface in the second case, is always combined with that from the pressure; whereas, in the former case, that arising from the pressure may be alone and uncompounded.

Add, that what is worn off a body, is ordinarily very little, with regard to the great number of times the body must have been raised during the *friction*, and all the little heights added together, which the body must have been raised to.

Hence, as the resistance from pressure may be single; and as the same always accompanies that arising from the magnitude of the surface, and is usually much the more considerable of the two, when it does accompany it: for these reasons, in most of the experiments that are made, it is the only one perceived, and the only one that needs to be considered.

But then, as it is possible, in certain cases, for the pressure to be very slender, and the number of parts to be rubbed, very great, it must be owned, there are cases wherein the *friction* follows, very sensibly, the proportion of the surfaces.

Dr. Desaguliers has treated fully of the *friction* of engines, carriages, &c. See his *Course of Experim. Philol.* vol. i. p. 133 to 138, and p. 182 to 254. See also p. 458 to 460.

FRICTION of the parts of fluids. See *RESISTANCE*, and *REDUCTION of fluids*.

FRICTION of ropes. See *CORNAGE* and *ROPES*.

FRICTION of wheels-carriages. See *WHEEL-CARRIAGE*.

FRICTION, in Medicine and Surgery, denotes the act of rubbing a diseased part with oils, unguents, or other matters, in order to ease, relieve, and cure it.

Frictions are much used of late in venereal cases. They prefer the applying of mercury externally by way of *friction*, to that of giving it internally, to raise a salivation.

There are also *frictions* with the flesh-brush, a linen cloth, or the hand only: for the effect of which last, see STROKING.

Frictions of any kind are a sort of exercise which contributes greatly to health: as they excite and stir up the natural warmth, divert distensions, promote perspiration, open the pores of the skin, and carry off stagnant humours.

The flesh-brush, Dr. Cheyne observes, is an exercise extremely useful for promoting a full and free perspiration and circulation. Every body knows the effect of carrying horses; that it makes them sleek, gay, lively, and active; so as even to be judged equivalent to half the feeding.

This it can no otherwise effect, but by assisting nature to throw off the recrement of the juices, which stop the free circulation, and, by constant friction, irritation, and stimulation, to bring the blood and spirits to the parts most distant from the seat of heat and motion: and to dump up the superficial muscles. And the same effect it would have in other creatures, and man himself, if managed in the same manner, and with the same care and regularity.

Persons, therefore, of weak nerves, and sedentary lives, would do well to supply the want of other exercise with spending half an hour morning, and night, in carrying and rubbing their whole body, especially their limbs, with a flesh-brush. But this means of health is most advantageously used when the *prima via* are most empty.

FRICTION, or rather **FRICTION**, in *Chemistry*, is the same with what in cookery we call *frying*; viz. the coction of certain matters in a pan, with the addition of some unctuous thing, as oil, fat, &c.

The *friction* of medicines is performed over a flow, moist, fire; and that of foods over a quick one.

FRIDAY, the sixth day of the week is called from Friga, a goddess worshipped by the Saxons on this day. It is a fast-day in the church of England, in memory of our Saviour's crucifixion, unless Christmas-day happens to fall on Friday, which is always a festival.

FRIDAY, *Gend.* See **PASSION-WEEK**.

FRIDTOLL, or **FRITHROW**, of the Saxon *frid*, peace, and *stol*, seat, in our ancient Writers, signifies a seat, chair, or place of peace, where criminals might find safety and protection.

In the charter of immunities confirmed to the church of St. Peter in York, ann. 5 H. VII. it is explained by *Cathedra quiescentis & pacis*.

Of these there were many in England; but the most famous was at Beverley, which had this inscription, *Hæc sedes lapidea Fredolito dicitur. i. e. Pacis Cathedra ad quam rursus fugientes perveniunt, omniumque habet securitatem*. Camden.

FRIENDLESS MAN, was the old Saxon name for him whom we call an outlaw.

The reason is, because he was, upon his exclusion from the king's peace and protection, denied all help of friends, after certain days. *Nam foris fecit amicus*.

FRIENDS ALIEN. See **ALIEN**.

FRIESLANDERS, in *Ecclésiastial History*, a sect of moderate ANABAPTISTS, deriving their name from *Frisland*, the country which they inhabit. See **WATERLANDIANS**.

FRIEZE, **FRIEZE**, or **FREEZE**. See **FREEZE**.

FRIGATE, in *Sea Affairs*, a ship of war, usually of two decks, light built, designed for swift sailing. When it hath but one deck, and consequently is of a smaller size, they call her a light *frigate*. See **RAVE**.

Frigates mount from twenty to thirty-eight guns, and are esteemed excellent cruisers. The name was formerly known only in the Mediterranean, and applied to a long kind of vessel navigated in that sea with sails and oars. The English were the first who appeared on the ocean with these ships, and equipped them for war as well as for commerce.

FRIGATE-BUILT denotes the disposition of the decks of such merchant ships as have a descent of four or five steps from the quarter deck and fore-castle into the waist, in contradistinction to those whose decks are on a continued line for the whole length of the ship, which are called gally-built. See **FLUSH-DECK**.

FRIGATOON, a Venetian vessel, commonly used in the Adriatic, built with a square stern, and without any foremast, having only a main-mast, mizen-mast, and bow-sprit.

FRIERATORY, among *Builders*, denotes a place intended to keep things cool in summer.

FRIHT. This passion has been known not only to cause but to cure diseases. Mr. Boyle mentions agues, gout, and sciatica, cured by this means. See **WORKS** abt. p. 82, &c.

It is a commonly known cure for the hicough, to put the patient in a sudden *fricht*.

Vol. II. N° 142.

FRIGID, **FRIGIDUS**, *cold*, is variously used. A *frigid style*, is a low, jejune manner of diction; wanting force, warmth of imagination, figures of speech, &c.

FRIGID ZONE, or *Frozen Zone*, in *Geography*. See **ZONE**. **FRIGIDITY** is also used in the same sense with **IMPOSTENCE**.

FRIGORIFIC, of *frigus*, *cold*, and *facis*, *I make*, in *Physics*, something that occasions cold.

Some philosophers, particularly Galendus, and other corpulcularians, denying cold to be a mere privation, or absence of heat, contend that there are actual *frigorific* corpuscles, or particles as well as fiery ones: whence proceed cold and heat. But later philosophers allow of no other *frigorific* particles beside those nitrous salts, which float in the air in cold weather, and occasion **FREEZING**.

FRILL, in *Falconry*, when a hawk trembles or shivers, they say the *frills*. **Dtd** Roll.

FRINGE-TREE. See **SNOW-DROP-TREE**.

FRINGILLA, in the *Linnean System of Ornithology*, the name of a large genus of birds of the general order of the passerines. The distinguishing characters of this genus are these: the tongue is smooth and even, the beak is of a conic, straight, sharp-pointed figure, and one mandible receives the other into the sinus of its basis. Of this genus are the CHAFFINCH, GOLD-FINCH, SPARROW, LINNET, &c.

FRINGILLAGO, in *Ornithology*, a name by which some have called the whole genus of the titmouse; but others have restrained it only to one species of them, which is the common larger kind called by us the ox-eye. This is much larger than any of the others, weighing near an ounce, whereas they seldom exceed three drams. Its head and throat are black, the cheeks white, the back green, the belly of a yellowish green, divided in the middle by a bed of black, which extends to the vent; the rump is of a bluish grey. The quill feathers are dusky, edged partly with blue, partly with white; the coverts blue, the greater tip with white. The exterior sides of the utmost feathers of the tail are white, of the others bluish; their interior sides dusky, the legs of a lead colour: the toes are divided to the origin; and the back toe of the whole genus of titmouse is large and strong. This bird builds in hollow trees, and lays ten eggs, though it sometimes visits the garden and does great mischief to the fruit. It has three cheerful notes which it begins to utter in the month of February. Pennant, Ray's Ornithol. p. 174.

FRINGILLAGO Americana carolinæ, in *Ornithology*, a name given by Mr. Ray to the American titmouse, otherwise known by its Brazilian name *guiracania*.

FRINGILLARIUS, *Accipiter*, in *Ornithology*, the name of a species of hawk called by some *nifus*, and in English the *parrot-hawk*.

FRIPPERY, a French term sometimes used in our language; properly importing the trade, or traffick, of old second-hand cloths and goods.

The word is also used for the place where such sort of commerce is carried on, and even for the commodities themselves. The company of *Frippiers*, or *Fripierres*, at Paris, form a regular corporation, of an ancient standing; and make a considerable figure among the companies of that city.

FRIST, a term among *Merchants* for selling goods upon credit.

FRIE, or **FRITT**, in the *Glass Manufacture*, is the matter, or ingredients, whereof glass is to be made; when they have been calcined, or baked in a furnace.

A salt drawn from the ashes of the plant kali, or from fern, or other plants mixed with sand, or flint, and baked together, makes an opaque mass, called by glassmen *frit*; probably from the Italian *frittura*, to fry, or because the frit, when melted, runs into lumps, like fritters, called by the Italians *frittoli*.

Frit, by the ancients, was called *ammonitrum*, or *ammonitrum*, of *ammon*, sand, and *niter*, nitre; under which name it is described by Pliny thus: fine sand from the Volturnian sea, mixed with three times the quantity of nitre, and melted, makes a mass called *ammonitrum*; which, being rebaked, makes pure glass. Hist. Nat. lib. xxxvi. cap. 26.

Frit, Neri observes, is only the calx of the materials which make glass: which though they might be melted, and glass be made, without thus calcining them, yet it would take up much more time. This calcining, or making, of *frit*, serves to mix and incorporate the materials together, and to evaporate all the superfluous humidity. The *frit*, once made, is readily fused, and turned into glass.

There are three kinds of *frits*; the first, *crystal frit*, or that for crystal metal; made with salt of pulvetric and sand.

The second, and ordinary *frit*, is made of the bare ashes of pulverine, or barilla, without extracting the salt from them. This makes the ordinary white, or crystal metal.

The third is *frit* for green glasses, made of common ashes, without any preparation. This last *frit* will require ten or twelve hours baking.

The materials in each are to be finely powdered, washed and sieved; then equally mixed, and frequently stirred together in the melting pot. For the rest, see GLASS, and CRYSTAL.

FRITHURGH. See FRIABURGH.

FRITH. See FRYTH.

FRITHGILD, was anciently the same with what we now call a *guild*, or *fraternity*, or company. See GILD.

FRITILLARIA *crassa*. See SWALLOW-TURT.

FRITILLARY, *fritillaria*, the *discoeped tulip*, and *cræmæ imperial*, in *Botany*, a genus of the *hexandria monogynia* class; its characters are these: the flower has no corolla; it is bell-shaped and hath six oblong petals; in the hollow at the base of each petal is situated a *nutlet*; and the flower hath six *filaments* standing near the style. In the centre is situated an oblong three-cornered germ, which afterwards becomes an oblong capsule with three lobes, having three cells, which are filled with flat seeds ranged in a double order. Linnaeus reckons five, and Miller nine species. There are vast varieties in the colours of the flower, when the plants are carefully propagated from seeds. They are by some propagated by roots, but the method by seeds is greatly preferable, as it produces much the greater number of roots, as well as the better flowers.

The seeds for this should be sowed from the finest flowers, and sown on some light fresh earth in flat shallow pans, or boxes with holes at the bottom, kept open by threads to let out the moisture. The seeds must be sown pretty thick, and covered with a quarter of an inch of earth: this is to be done in the beginning of August. The pans or boxes are then to be set in a place where they may have the morning's sun, till about eleven o'clock, and if the season proves dry, they must be watered, and always carefully kept clear of weeds.

Toward the latter end of September the boxes must be removed into a warmer situation, and placed under shelter of a hedge or under a south wall, and they are here to remain till the middle of March, by which time the plants will be come up an inch high. They are now to be removed into a shady situation, and are to remain there the whole summer. About the beginning of August, a bed of fresh earth is to be prepared, on which the earth of the pans and boxes containing the roots of the plants is to be strewed, after the leaves are all dead: this is to be covered one fourth of an inch thick with fine fresh earth evenly sifted on, and in this state they are to remain till they flower, which is generally the third year from the sowing. When they are in flower, the finest kinds should be marked with sticks, and their roots planted out into separate beds.

As soon as the leaves are decayed they should be carefully weeded, and thin off-sets taken up and transplanted. Miller.

For an account of the other species of this genus, see CROWN IMPERIAL.

FRIXION. See FRICTION.

FRIZE, or FRIeze, in *Architecture*, a part of the entablature of columns, more usually written and pronounced FRIZZE.

FAIR, or FREEZE, in *Commerce*, a kind of woollen cloth, or stuff for winter wear, being *friezed*, or knapt, on one side; whence, in all probability, it derives its name.

Of *frieze*, some are crossed, others not crossed: the former are chiefly of English manufacture, the latter of Irish.

FRIZING of cloth, a term in the *Woollen Manufacture*, applied to the forming of the knap of a cloth, or stuff, into a number of little hard horns, or prominences, covering almost the whole ground thereof.

Some cloths are only *friezed* on the back-side, as black cloths; others on the right side, as coloured and mixed cloths, ratens, bays, friezes, &c.

Friezing may be performed two ways; one with the hand, i. e. by means of two workmen, who conduct a kind of plank that serves as a *friezing* instrument.

The other way is by a mill, worked either by water, or a horse; or, sometimes, by men. This latter is esteemed the better way of *friezing*, because the motion being uniform and regular, the little knobs of the *friezing* are formed more equally and regularly.

The structure of this useful machine is as follows:

The three principal parts are, the *friezer*, or *crisper*; the *friezing-table*; and the *drawer*, or *beam*. The two first are two equal planks, or boards, each about ten feet long, and fifteen inches broad; differing only in this,

that the *friezing-table* is lined or covered with a kind of coarse woollen stuff, of a rough, sturdy knap, and that the *friezer* is incrustated with a kind of cement, composed of glue, gum Arabic, and yellow sand, with a little aqua vita, or urine. The beam or drawer, thus called, because it draws the stuff from between the *friezer* and *friezing-table*, is a wooden roller, bevel all over with little fine, short points or ends of wire, like those of cards used in carding of wool.

The disposition and use of the machine are thus: the table stands immovable, and bears or sustains the cloth to be *friezed*, which is laid with that side uppermost on which the knap is to be raised. Over the table is placed the *friezer*, at such distance from it as to give room for the stuff to be passed between them; so that the *friezer*, having a very slow, semi-circular motion, meeting the long hairs or knap of the cloth, twills and rolls them into little knobs or horns, while, at the same time, the *drawer*, which is continually turning, draws away the stuff from under the *friezer*, and winds it over its own points.

All that the workman has to do while the machine is going, is to stretch the stuff on the table as fast as the *drawer* takes it off, and from time to time, to take off the stuff from the points of the *drawer*.

It has already been observed, that the *friezing-table* is lined with stuff of a short, stiff, stubby knap; the use whereof is, to detain the cloth between the table and *friezer*, long enough for the grain to be formed, that the *drawer* may not take it away too readily; which otherwise must be the case, inasmuch as it is not held by any thing at the other end.

It were needless to say any thing particular of the manner of *friezing* stuff with the hand, it being the aim of the workmen to imitate, as near as they can, with their wooden instrument, the slow, equable, and circular motion of this machine. It needs only be added, that their *friezer* is but about two feet long, and one broad; and that, to form the knap more easily, they moisten the surface of the stuff lightly with water, mingled with whites of eggs, or honey.

FRIZONE, in *Ornithology*, a name by which many call the *COCCOTHRAXAUSTES* or *grofs-beak*, called also in English the *hawfinch*.

FROBENIUS's *æthereal spirit*. See ÆTHER and SPIRIT.

FROG, *rana*, in *Zoology*, a genus of reptiles in the class of amphibious animals: the characters of it are, that the body is naked, without a tail, and furnished with four legs.

The feet of the *frogs* are webbed, for the better swimming, and it has very strong muscles in the hinder part of its body to assist it in leaping. The lungs of the *frog* are different from those of all other animals: they are only a sort of membranaceous bladders, with several tubercles, by means of which they resemble the fruit of the fir, or pines: these, when once inflated, do not immediately become flaccid, as in other animals, but remain in that state as long as the creature pleases. The creature can remain a long time under water, and has been kept so for several days, by tying it down, and received no hurt from it. It is a very long-lived animal; and even if its belly be opened, and the intestines and all the viscera taken out, it will continue leaping, and all its other motions, as if nothing had happened to it, for a considerable time; but if the nerve of one of the hinder legs be cut, it instantly loses all power of using that limb. Ray's *Synop. Quad.* p. 247.

Frogs, the *generation of*, was very nicely inquired into by the sagacious Læwenhook. He found, by repeated observations, that the male in copulation only fits upon the female, not being joined to her, nor having any apparent penis. At the time that the female *frog* drops her spawn, the male also throws out his semen, which is to be placed under the eggs, as the semen of fishes that want the penis is cast under the eggs or spawn of their females, that the animalcules in it may impregnate the eggs. The animalcule in the male-seed has its way to make into a certain point of the egg of the female, or else that egg is unfruitful; and this is the reason why the animalcules in the male semen are so prodigiously more numerous than the eggs of the female, because vast multitudes of them must necessarily be lost. The reflexile and vasa deferentia of *frogs* are very evident to any one used to anatomical inquiries, on opening the creature; and these contain vast numbers of very vigorous animalcules at the time when the creature is to produce its young, which is in April, but at other times they are not so numerous or lively.

The *frog* differs from all creatures in the manner of its generation. It no way resembles any of the quadrupeds in this particular; and though in some sort it approaches to the nature of fish, yet it differs from them also in many things. The egg of the *frog* is a small black spot, enveloped

enveloped in a mucilaginous substance; in this egg is contained the embryo *frog*, which, on the breaking of the egg in hatching, comes forth in the form of a tadpole. This young animal is for some time nourished by the gelatinous matter which envelopes the eggs, but it does not consume the whole of it; for the particles of water making way by degrees into it, divide its parts, and it soon becomes expanded, frees itself from the living animals, and floats on the surface of the water, or at a small depth in it, in form of a thin cloud; this, though it now no longer serves for food to the young creature, is however of some service to it, serving it as an asylum, or place of rest and safety, when tired with swimming.

The egg of the *frog*, therefore, is, in some degree, analogous to that of an insect of the winged kind, which is to go through a metamorphosis before it arrives at its perfect state; for it hatches into the tadpole, as the egg of a butterfly into a caterpillar, and arrives at that its ultimate state, after a determinate time spent in the other. In this it differs from the generation of fishes, the eggs of whose spawn hatch into perfect fishes, which go through no change; and it differs from all in the gelatinous substance which envelopes the egg, and serves as the first food to the fetus.

The eggs are indeed, when nicely examined, found to be inclosed in a double liquor, or more pellucid and thin one within the gelatinous one, which serves as the general covering to the whole series of eggs; and it is this thin one which it principally feeds on when first hatched, and which serves to the same purpose as the white of an egg in the fowl kind. Ray, *ii. f. 109.*

This creature bears the experiments of the air-pump better than most other animals. It will breathe some time after the extraction of the air, but at length the visible motion of the throat will cease, and the body swell a little. After three hours lying in this condition, when no farther sign of life appears, if the animal be placed in the open air, a few hours will recover it to its former life and vigour. The same animal put into a receiver exhausted of the air, but nearly filled with water, will live many hours under the water, and seem to respire, but in five or six hours it will die. The larger and lusher *frogs* live longer than the young ones in the receiver. Phil. Trans. N^o 62.

The *FROG* affords the curious in microscopic observation a very beautiful view of the circulation of the blood; but the method of examining it to advantage was never hit upon till the contrivance of the late ingenious Dr. Stuart for that purpose. This he did by the solar microscope in the following manner. The looking-glass, tube, and convex lens, are the same in this, as in the common solar microscope; but instead of the little pocket microscope of Willson, he used the belly-part of the common large reflecting one, fixed horizontally on a pedestal, just at an equal height with the tube. This stands on a little shelf made to support it; and to its snout, which lies on a level with the tube, the magnifiers are screwed: the object being extended and fastened with fibres and pins on a frame contrived for that purpose, is applied between the tube and the magnifier, whereby the sun's rays, reflected from the looking-glass, through the tube, upon the object, pass on through the magnifier, and exhibit upon the screen an image of the object most prodigiously enlarged. Baker's Microsc. p. 132. To view a *frog* with this apparatus, the skin of the belly is to be opened from near the anus to the throat, and then giving it a little snip sideways both at the top and bottom, and flicking a fish-hook into each corner of the skin, it was easily extended before the microscope, and shewed on the screen the most beautiful view imaginable of the veins and arteries of the skin, with the blood circulating through them. In the arteries thus viewed, the blood is seen to stir, and recede a little at every pulsation by the dilatation, and rush forcibly on again by the contraction of the heart; while in the veins it ever kept the same equable and uniform current, with a surprising rapidity; and when the screen was removed farther back, and the object by that means more enlarged, the alternate expansion and contraction of the sides of the arteries were very visible. After this, the abdomen of the *frog* being opened, and the muscles of it being extended before the microscope in the same manner as the skin was, the structure of these muscles is beautifully seen, being all made up of bundles of transparent strings of fibres, all lying parallel to one another, and joined by a common membrane.

These fibrils or fibres appeared also through their whole length made up of roundish vesicles, and resembled ruffles divided longitudinally; but there is no certainty of any circulation being seen in these.

When this has been sufficiently examined, a part of the

creature's guts being pulled out and extended with this mesentery, there is seen the finish of all views of the circulation of the blood. Words are not able to describe this wonderful scene. The blood is seen passing through numberless vessels at one and the same instant, in some one way, and in others directly the contrary. Several of the vessels are thus magnified to more than an inch in diameter, and the globules of the blood rolling through them, appear near as large as pepper-corns; while in many of the minutest vessels only single globules were able to find their passage, and that too by changing their shape into an oblong spheroid. The pulsation and acceleration of the blood in the arteries are thus also very beautifully seen. As the animal under examination grows languid and near expiring, the blood in the arteries will often stop on a sudden, and seem as if it were coagulating, and will then run back for some time; after which it will again recover its natural course with a great deal of rapidity. A due consideration of these particulars may possibly account for the intermissions, starts, and irregularities, in the pulse of persons near death. Baker's Microscope, p. 136.

FROG, among *Partriers*, the same with *froth*. See **FRASH**.

FROG's bit, in *Batory*. See **HYDROCHARIL**.

FROG, bull. See **BULL-FROG**.

FROG-fish, in *Icthyology*, an English name for the *BANANAFICATRIX*, or *LOPHIUS*. See **SEA-DEVIL**.

FROG-fish of *Surinam*, it produced by the transformation of a *frog* into a fish. The *frog*, in its first state, is spotted with brown, yellow, and green, but paler on the belly; the hinder feet are webbed like those of a goose, but the fore-feet are without webs; at the first change this *frog* undergoes is by the growing out of a tail; after which it gradually acquires the shape of a fish, the two fore-feet decreasing and perishing by degrees, and then the hinder legs; and, at length, the *frog* is changed into a perfect fish. The Indians and Europeans of *Surinam* call these fishes *fakies*; they are cartilaginous, and of a substance like our *myxia*, and very delicate food. A bone or cartilage runs down the back, with small bones all over the body, which is divided into equal parts; they are adorned with beautiful scales, are first of a darkish colour, and afterwards grey. See an account of the several transformations of this *frog*, illustrated with drawings, and of the transformation of fishes into *frogs*, in Phil. Trans. vol. ii. p. 2. art. 60. p. 653, &c.

FROG. See **RANUNCULUS** *veridis*.

FRONDES, among *Botanists*. See **LEAF**.

FRONT, the forehead, or that part of the face above the eyebrows.

The word is formed of the Latin *frons*; and that from the Greek *φρῶν*, to think, perceive; of *φρον*, ment, the mind, thought. Martinus, to make out this etymology, observes, that from the forehead of a person we perceive what he is, what he is capable of, and what he thinks of. Dr Laurens chuses to derive it from *frere*, because it bears the marks of what we have in our head.

FRONT is also used where several persons, or things, are ranged side by side, and shew their *front*, or fore parts.

FRONT, in *Architecture*, denotes the principal face, or side of a building; or that presented to their chief aspect, or view.

FRONT, in *Fortification*. See **FACE** and **TENAILLE**.

FRONT of a *regiment*, in *Military Language*, denotes the foremost rank of a battalion, squadron, or any other body of men.

To *front* every way, is when the men are faced to all sides. See **FILE-LEADERS**.

FRONT of a *camp* is the line that determines its extent, and in which are placed the colours and standards of the troops that occupy the *CAMP*.

FRONT, in *Opticks*, a projection or representation of the face, or fore-part of an object, or of that part directly opposite to the eye; called also, and more usually, **ORTHOGRAPHY**.

FRONT, line of the. See **LINE**.

FRONT scale. See **SCALE**.

FRONTAL, in *Architecture*, a little fronton or pediment, sometimes placed over a small door or window.

FRONTAL, **FRONTLET**, or *Brow-band*, is also used in speaking of the Jewish ceremonies.

This *frontal* consists of four several pieces of vellum, on each whereof is written some text of scripture: they are all laid on a piece of a black calf's leather, with thongs to tie it by. The Jews apply the leather with the vellum on their foreheads, in the synagogue, and tie it round the head with the thongs.

FRONTALE, in *Anatomy*. See **O. FRONTOIS**.

FRONTALE, or **FRONTAL**, in *Medicine*, an external form of remedy, applied on the forehead and temples, with a bandage, for the cure of the head-ach, *megrim*, vapours, delusions on the eyes, &c.

Frontals are composed of roses, elder flowers, betony, marjoram, lavender, camphire, &c. wrapped in linen cloth, and applied over the forehead and temples.

There are also *frontals* in manner of liniments, made of unguentum populeum, and extract of opium, or paltes, powders, &c.

In *frontals* applied to ease the violence of the head-ach, in the heights of fevers, they frequently mix the kernels of cherries.

FRONTALES, in *Anatomy*, two muscles one on each side the forehead, commonly supposed to spring from the skull, but not known to arise from the occipital muscles; or rather, it appears that the *frontalis* and *occipitalis*, are only one continued digastric muscle, on each side, moving the scalp and skin of the forehead and eyebrows. See *Tak. Anat. (Musk.)* fig. 1. N° 1.

The *frontalis* begin to be thus denominated after they have begun to pass the coronal suture, with fibres passing obliquely to the eyebrows, where they terminate, and in the lower part of the skin of the forehead.

They have each two appendages: the superior, or external, is commonly fixed to the bone of the nose; the lower is fixed to the os frontis, and is, by Volcherus Coltes, made a distinct muscle, and called *corrugator*, from its use in drawing the eyebrows to each other, and wrinkling the forehead.

FRONTATED, a term used by *Botanists*, to express that the petalium, or leaf of a flower, grows broader and broader; and at last, perhaps, terminates in a right line; in opposition to *capitulated*, which expresses, that the leaves terminate in a point.

FRONTEVAUX, *order of*. See **FONTEVAUD**.

FRONTIER, the border, confine, or extreme, of a kingdom, or province; which the enemies find in front when they would enter the same. Thus we say, a *frontier* town, *frontier* province, &c. *Frontiers* were anciently called *marche*.

The word is derived from the French *frontiere*, and that of the Latin *frons*, as being a kind of front opposed to the enemy. Skinner derives *frontier* from *frons*; inasmuch as the *frontier* is the exterior, and most advanced part of a state; as the *front* is that of the face of a man.

FRONTIS is, in *Anatomy*, the bone of the forehead. See *Tak. Anat. (Musk.)* fig. 1. lit. a. See **Os Frontis**.

FRONTIGNAC wine is so called, from a town of Languedoc in France, situated sixteen miles south-west of Montpellier, remarkable for producing it.

FRONTISPIECE, in *Architecture*, the portrait, or principal face, of a fine building.

The word is formed of the Latin *frons* and *spicium*, q. d. *frons hominis inspicilla*.

The *frontispiece* of the Louvre is the finest piece of architecture in France.

Hence, also, by a figure, we say, the *frontispiece* of a book, meaning an ornament, with an engraven title on the first page.

FRONTLET. See **FRONTAL**.

FRONTLET, *Arm*, in *Gunwory*, is a piece of a plank three inches thick, a foot long, and seven or eight inches high, with a round cavity underneath, to fit the outside of the gun, and having a small slit to see the object through it. It is placed upon the vent-field of the gun, when it is pointed in a BATTERY.

FRONTON, in *Architecture*, an ornament, among us more usually called **PEDIMENT**.

FROST, an excessive cold state of the weather, whereby the motion and fluidity of liquors is suspended; or, it is that state of the air, &c. whereby fluids are converted into ice. See **COLD** and **FREEZING**.

Metals contract in *frö*. Monf. Azout found, by experience, that an iron tube, twelve feet long, lost two lines of its length, upon being exposed to the air in a *frö* night; but this we suppose wholly the effect of the cold. *Frö* does not contract fluids, as was formerly imagined; on the contrary it swells, or dilates them, by nearly a tenth of their bulk. See **ICE**.

Scheffer assures us, that in Sweden, the *frö* pierces into the earth two cubits, or Swedish ells, and turns what moisture is found therein into a whitish substance, like ice; he adds, the running waters freeze to a greater depth, even to three ells or more; but those that have a current, less; and rapid waters, and bubbling springs, never freeze, even there.

Olearius assures us, that in the city of Moscow he observed the earth to be cleft by the *frö* many yards in length, and a foot broad. Scheffer mentions sudden cracks or rifts in the ice of the lakes of Sweden, nine or ten feet deep, and many leagues long; and adds, that the rupture is made with a noise not less terrible than if many guns were discharged together. By such means the fishes are furnished with air; so that they are rarely found dead.

In the great *frö* in 1683, oaks, alders, walnut-trees, &c. Mr. Bohart tells us, were miserably split and cleft, so that one might see through them; and this, frequently, with terrible noises, like the explosion of fire-arms; the clefts were not only in the bodies, but continued to the larger boughs, roots, &c. See an inquiry into the circumstances and causes hereof in the Philosoph. Transact. N° 165.

The natural histories of *frö* furnish very extraordinary effects thereof. The trees are frequently scorched, and burnt up, as with the most excessive heat; of which there are divers instances in so warm a climate as that of Provence.

The close of the year 1708, and the beginning of 1709, were remarkable, throughout the greatest part of Europe, for a severe *frö*. Dr. Detham says, it was the greatest in degree, if not the most universal, in the memory of man: it extended throughout England, France, Germany, Denmark, Italy, &c. but it was scarcely felt in Scotland or Ireland. All the orange-trees, and olives, in Italy, Provence, &c. and all the walnut-trees throughout France, with an infinity of other trees, perished by this *frö*. They had a kind of gangrene that grew on them; which Monf. Gauteron takes to have been the effect of a corrosive salt corrupting and destroying their texture. He adds, there is so much resemblance between the gangrene befalling plants through *frö*, and that which the parts of animals are liable to, that they must have some analogous cause. Corrosive humours burn the parts of animals; and the aerial nitre condensed has the same effect on the parts of plants. *Potentillæ lignis adortæ*. Mémoires de l'Académie Royale des Sciences, an. 1709.

In England, the greatest sufferers in the animal kingdom, Dr. Detham observes, were birds and insects; particularly larks, and robin-red breasts; much the greatest part of which perished. But the vegetables were far the greater sufferers; few of the tender sorts escaped; hays, hollies, rosemary, cypress, alatern, phillyrea, arbutus, laurelles, and even furze, with most of the fruitest herbs, as lavender, abrotanums, rue, thyme, &c. Mr. Bohart informs us, were generally destroyed. The same winter adds, that the sap of the fine wall-fruit was so congealed and disordered, that it ligured in the limbs and branches, and produced disorders like to chilblains in human bodies, which, in many parts of trees, would turn to mortifications; and that the very buds of the finer trees, both the leaf buds, and blossom-buds, were quite killed, and dried into a farinaceous matter.

Dr. Detham relates it, as a common observation, that vegetables suffered more in this winter from the sun, than the *frö*; in that the sun-shine melting the snow, and opening the ground, left them more exposed to the rigours of the ensuing night; and at a meeting of the Royal Society, it was observed, that the calamities which befall trees, arose, not purely from their being frozen, but, principally, from the winds shaking and rocking them, when they were so; which rent and parted their fibres. Phil. Trans. N° 324.

In very cold countries meat may be preserved by the *frö* six or seven months, and prove tolerable good eating. See Captain Middleton's Observations made in Hudson's Bay, in the Phil. Trans. N° 405. sect. 2.

In that climate the *frö* seems never out of the ground, it having been found hard frozen in the two summer months.

Brandy and spirits of wine, set out in the open air, freeze to solid ice in three or four hours. Lakes and standing waters, not above ten or twelve feet deep, are frozen to the ground in winter, and all the fish therein perish.

But in rivers, where the current of the tide is strong, the ice does not reach to deep, and the fish are preserved. Springs have never yet been found free from FREEZING, though lying ever so deep; so that the water used is melted snow and ice. See *ibid.*

The great power of *frö* on vegetables is a thing sufficiently known; but the difference between the *frö* of a severe winter, and those which happen in the spring mornings, in their effects on plants and trees, were never perfectly explained, till by Mess. Du Hamel, and De Buffon, in the Memoirs of the Paris Academy.

The accurate knowledge of vegetables, which is so material a part of agriculture, as to deserve the attention of all who wish well to their country, is however a thing only to be arrived at in length of time, and by a great number of experiments, such as no one man's life can give him opportunities of making; and even those which have been made seemingly with the greatest care and caution in one place, and have served for the establishment of rules with one author, have been found to succeed very differently, and to give very different ideas in another place, and to another person.

The *frö*s of severe winters are much more terrible than those of the spring, as they bring on a privation of all the products

products of the tenderer part of the vegetable world; but then they are not frequent, such winters happening but once perhaps in an age, and the *frösts* of the spring are in reality greater injuries to us than these, as they do as great injuries, though not so terrible as the others, and these are every year repeated.

In regard to trees, the great difference is this, that the *frösts* of severe winters affect even their wood, their trunks and large branches; whereas those of the spring have only power to hurt the buds.

The winter *frösts* happening at a time when most of the trees in our woods and gardens have neither leaves, flowers, nor fruits upon them, and have their buds too hard as to be proof against slight injuries of weather, especially if the preceding summer has not been too wet; in this state, if there are no unlucky circumstances attending, the generality of trees bear moderate winters very well; but hard *frösts*, which happen late in the winter, cause very great injuries, even to those trees which they do not utterly destroy. These are, 1. Long cracks following the direction of the fibres. 2. Parcels of dead wood, included round with wood yet in a living state.

And, 3. That disposition which the foresters call the double blea, which is a perfect circle of blea, or soft white wood, which, when the tree is afterwards felled, is found covered by a circle of hard and solid wood.

The BLEA is in its natural state an outer circle of white and imperfect wood encompassing the hard and more perfect wood of the tree, and surrounded by the bark, and is easily distinguished in most species from the hard wood or heart of the tree by its different colour, and want of hardness.

The number of observations which Mr. Reaumur made of the blea of trees in different parts of France, all shewed him the false blea under the same number of annual circles of the after-growth of the tree; and these being counted, proved just as many as the number of years since 1709; whence he very justly concluded, that all the false blea be found throughout the kingdom, was the effect of the severity of this one hard winter. And it is very evident, that this false blea is that part of the tree, which in the year 1709 was the true and natural blea, and which the severity of the *frösts* of that winter prevented from ever becoming sound and solid wood, but left it to become more weak and defective for a succession of years; during which the several annual circles of supervenient blea all became sound and perfect wood in their natural state.

It appears very plain, that the blea must be that part of the wood which suffers most, because it is the outer wood of all, and itself makes a covering for the inner part; and add to this, that it is of itself of a much less compact texture, and contains more juices for the *frösts* to act upon. Another accident attending trees from very severe *frösts* is, that they are sometimes split by them according to the direction of their fibres, and this often with a very loud crack.

It is not uncommon in large forests to meet with trees that have been thus split, and which having outlived the winter that occasioned it, are found to have a long rib marking the place where the crack was, and forming a sort of cicatrix or scar over the wound. This cicatrix or rib is however only superficial, and wherever it is, the crack is still found remaining under it in the tree; for though the bark and blea can in this manner consolidate and form a covering for a wound, the fibres of the solid wood, when once broken or separated, never close again. It is the general opinion of the workmen, that all these cracks in timber are the effects of *frösts*; and it is very easy to conceive, that it may be natural for *frösts* to effect it, as it is well known that all frozen liquors take up more room, than they did while in a fluid state. See FREEZING. It is not certain, however, that all the cracks in timber are from this cause, many of them may have been occasioned merely by a redundancy of sap.

The opinions of authors about the exposition of trees to the different quarters, have been very different, and most of them grounded on no rational foundation. Many are of opinion that the effects of *frösts* are most violently felt on those trees, which are exposed to the north; and others think, the south, or the west, the most strongly affected by them. There is no doubt, but the north exposure is subject to the greatest cold. It does not, however, follow from this, that the injury must be always greatest on the trees exposed to the north in *frösts*; on the contrary, there are abundant proofs among the preceding observations, that it is on the south side that trees are generally most injured by *frösts*; and it is plain from repeated experiments, that there are particular accidents, under which a more moderate *frösts* may do more injury to vegetables, than the most severe one which happens to them under more favourable circumstances.

It is plain from the accounts of the injuries trees received by the *frösts* of 1709, that the greatest of all were owing to repeated false thaws, succeeded by repeated new *frösts*. But the *frösts* in the spring season furnish abundantly more numerous examples of this truth; and some experiments made by Mr. de Buffon, prove incontestably, that it is not the severest cold, or most fixed *frösts*, that does the greatest injury to vegetables.

This is an observation directly opposite to the common opinion, yet is not the less true, nor is it any way discordant to reason. We find by a number of experiments, that humidity is the thing that makes *frösts* fatal to vegetables, and therefore every thing that can occasion humidity in them, exposes them to these injuries, and every thing that can prevent or take off an over proportion of humidity in them; every thing that can dry them, though with ever so increased a cold, must prevent or preserve them from those injuries. Numerous experiments and observations tend to prove this. It is well known that vegetables always feel the *frösts* very desperately in low places where there are fogs. The plants which stand by a river side, are frequently found destroyed by the spring and autumnal *frösts*, while those of the same species, which stand in a drier place, suffer little, or perhaps not at all by them; and the low and wet parts of forests are well known to produce worse wood than the high and drier; and the coppice wood in wet and low parts of common woods, though it push out more vigorously at first than that of other places, yet never comes to so good a growth; for the *frösts* of the spring killing these early top-shoots, obliges the lower part of the trees to throw out lateral branches; and the same thing happens in a greater or lesser degree to the coppice wood that grows under cover of larger trees in great forests; for here the vapours not being carried off, either by the sun or wind, stagnate and freeze, and in the same manner destroy the young shoots as the fogs of marshy places. It is a general observation also, that the *frösts* is never so fatal to the late shoots of the vine, or to the flower-buds of trees, except when it follows heavy dews, or a long rainy season, and then it never fails to do great mischief, though it be ever so slight.

The *frösts* is always observed to be more mischievous in its consequences on newly cultivated ground, than in other places; and this is because the vapours which continually arise from the earth find an easier passage from those places than from others. Trees also which have been newly cut, suffer more than others by the spring *frösts*, which is owing to their shooting out more vigorously. *Frösts* also do more damage on light and sandy grounds, than on the tougher and firmer soils, supposing both equally dry; and this seems partly owing to their being more early in their productions, and partly to their lax texture, suffering a greater quantity of vapours to transpire.

It also has been frequently observed, that the side-shoots of trees are more subject to perish by the spring *frösts*, than those from the top; and Mr. Buffon, who examined into this with great accuracy, always found the effects of the spring *frösts* much greater near the ground than elsewhere. The shoots within a foot of the ground quickly perished by them; those which stood at two or three feet high, bore them much better; and those at four feet and upwards frequently remained wholly unharmed, while the lower ones were wholly destroyed.

There are a series of observations, which have proved beyond all doubt, that it is not the hard *frösts* which do much hurt plants, as those *frösts*, though less severe, which happen when they are full of moisture; and this clearly explains the account of all the great damages done by the severe *frösts* being on the south side of the trees which are affected by them, though that side has been plainly all the while less cold than the north. Great damage is also done on the western sides of trees and plantations, when, after a rain with a west wind, the wind turns about to the north at sun-set, as is frequently the case in spring, or when an east wind blows upon a thick fog before sun-rising. Mem. Acad. Scien. Par. 1737.

PROST, hard, or white PROST, Prunus, is the new frost, or congealed, early in cold mornings; chiefly in autumn. Hard-frost, Mr. Regis observes, consists of an assemblage of little parcels of ice crystals, which are of various figures, according to the different disposition of the vapours, when met, and condensed, by the cold.

Dew is, in all appearance, the matter of hard-frost; though many of the Cartesianians will have it formed of a cloud; and either congealed in the cloud, and so let fall; or ready to be congealed as soon as it arrives at the earth.

FROST-split, a phrase used by our farmers to express such trees as have large cracks in their trunks and branches, rendering

rendering them unfit for the uses they would otherwise have sold for, and by that means greatly debasing their value. It has been pretended by some, that these rents and cracks in trees were owing to other causes; but we have had innumerable instances, and these well recorded, of the immediate effect of hard frosts on the strongest trees, spoiling them in this manner; and it appears very rational to suppose all these injuries do really come by the same means, and are properly called by this term. Vide *supra*, and the Phil. Trans. N^o 165.

FROTH, a white, light substance, formed on the surface of fluids, by vehement agitation.

Froth consists wholly of little spherules, or globules; and, accordingly, may be defined, an assemblage of aqueous aëreal bubbles.

FROTH, in the *Manège*, is a moist white matter that oozes from a horse's mouth, otherwise called foam. A horse that by champing on his bridle, throws out a great deal of froth, is judged to be a horse of metal and health, and to have a cold fresh mouth.

FROTH-SPIT, or *cuckoo-spit*, a name given to a sort of white froth, or spume, very common in the spring, and first months of the summer, on the leaves of certain plants, particularly on those of the common white field lychnis, or catch-fly, thence called by some *spitting poppy*. All writers on vegetables have taken notice of this froth, though few have understood the cause or origin of it, till of late. Many imagined it an exhalation from the earth; some have esteemed it, as its name expresses, the saliva of the cuckoo; others, the extravasated juices of the plant, and some a hardened dew. But all these are erroneous opinions, and the account of it is, that it owes its origin to a small insect, called by some the flea-grass-hopper, which applies its anus close to the leaf, and discharges upon it a small drop of a white viscous fluid, containing some air in it, and, therefore, soon elevated into a bubble. Before this is well formed, it deposits such another drop, and so on, till it is every way overwhelmed with a quantity of these bubbles, which form this froth. See *CICADOLA*.

FROUNCE, in the *Manège*, a disease in horses, when small warts or pimples arise in the middle of the palate, which are very soft and sore, and sometimes breed in the lips and tongue.

This disorder is occasioned many ways; sometimes by eating wet hay, whereon rats or other vermin have pissed; by drawing frozen dust into their mouths among the grass, &c.

As to the method of treatment, it consists in letting them bleed in the two largest veins under the tongue, and washing the sores with vinegar and salt, or with ale and salt, till they bleed.

FRIGOR, in *Falunary*, a disease incident to hawks, arising from moist and cold humours falling down to the palate and root of the tongue; by which means they lose their appetite, and cannot close their clasp. Washing with alum-water, lemon-juice, &c. is held good for it.

FROWER, an edged tool, used to cleave wood into laths.

FRÖWEY, a term used by workmen for timber, which is evenly tempered, and works freely without tearing.

FROZEN, or *FRIGID RARE*. See *ZONE*.

FROZEN SCUM. See *OCEAN*.

FROZEN SWEETS. See *WATERS*.

FRUCTIFEROUS properly denotes any thing that produces fruit; but in a more large and figurative sense, is used by lord Bacon, and others, for such experiments in natural philosophy, as prove advantageous to the experimenter in point of gain or profit.

FRUCTIFICATION of plants. *Fructification* is defined by Linnaeus to be the temporary part of a vegetable appropriated to generation, terminating the old vegetable, and beginning the new. It consists of the following seven parts; viz. the CALYX, COROLLA, STAMEN, PISTILLUM, PERICARPIMUM, SEMEN or SEED, and RECEPTACULUM.

The organs of *fructification* in plants are the *perianth*, generally contained in the middle of flowers; and the *stamens*, which surround it, furnished at their extremities with little bodies; these the botanists term the first the *stamens*, the second the *stamina*, and the third, or heads of the *stamina*, the *anthers*, or *apices*. See *FLOWER*.

The apices contain the *serminal sacculum*, a fine subtle matter analogous to the *serminal sacculum* in animals; the *stamina* serve only for their support, and to convey nutrition to them; and the *stamens* is the part destined to receive this *serminal*, and convey it to the seeds.

It is upon these principles that the excellent Linnaeus has founded his system of the vegetable world, and formed his classes. This author's work has been received by the learned world in all nations with the respect it merits; but has been too generally censured among the slighter professors in botanical researches, as abstruse, difficult, and unintelligible. The viewing of these things in a new

light, and the necessity of making new words to convey new ideas, have indeed given this great attempt something of the face of an abstruse piece; but presenting a few general hints, it may not be difficult to vindicate the author from the heavy charges which have been laid against him, and give the English reader a clear and perfect view of his work.

From the structure and use of the *stamens*, *stamina*, and *apices*, it is easy to conceive that the former must be accounted the *female*, and the two latter the *male parts* of flowers. This is the great basis of his system. To express the different combinations of these in the different classes of plants, by formal descriptions to each, had been tedious, and an excessive burden to the memory; to avoid this, he has excellently contrived the comprising that description, or general character, in one word. It is easy to conceive there could be no word already in use, that could express what had never before been thought of; he was therefore necessitated to invent new ones for this purpose. He has ventured therefore to form twenty-four such, for his classes, which are of that number, and has taken them from that language which all the learned have ever used on the same occasion, the Greek; and this with the least ostentation or show of learning imaginable; in short, to understand all these, there is no need of knowing more Greek than that *andros* signifies a man, or any thing male; and *gynē*, a woman, or female; that *diogenes* is *propter effectum diogenis*, a breeder; and thence *diogenes*, brotherhood, or community; that *andros* is together; *gynē*, generation, or origin; and *stachys*, a leaf, or habitation; that *monos* signifies many; *diogenes*, marriage; and *apocryptus*, hidden, or concealed; and that the numbers one, two, three, four, five, six, seven, eight, nine, ten, twelve, and twenty, or their derivatives, once, twice, &c. are expressed by the Greek words, *monos*, *dis*, *tris*, *tetras*, *pentas*, *hexas*, *septas*, *octas*, *decas*, *duodecas*, *icetas*, *icetas*, *icetas*, *icetas*, *icetas*, *icetas*; these needs, I say, no more knowledge of Greek than this, to understand perfectly the meaning of all the terms this author, to avoid tedious descriptions, has used as the characters of his classes. To begin with certainty and regularity.

He first divides the whole vegetable world into such species as have their flowers visible and obvious to the eyes, and such as have them invisible, or at the utmost scarce discernible.

Those which have them visible, he then divides again into such as have the *stamina*, *apices*, and *stamens*, that is, the male and female parts of *fructification* in the same flower: these he, for that reason, calls *hermaphrodite* flowers.

And such as have the male and female parts of *fructification*, that is the *apices* and *stamens*, either in different flowers upon the same stalk, or upon different plants of the same species: these he calls the distinct male and female flowers.

Those which have the different organs of *fructification* lodged in the same flower, he again divides into such as have the *stamina* in no part growing together, or cohering to one another; and such as have them either growing together or cohering together mutually in some part, either with one another, or with the *stamens*.

Those which have them in no part cohering either with the *stamens*, or with one another; he again subdivides into such as observe no exact or accurate proportion of length one among another; and such as have ever two of the *stamina* shorter than the rest.

From these general divisions he descends to his particular classes, of which he establishes twenty-four. See the several classes and orders in the Linnaean system illustrated by figures in *Tables I. II. III. IV. V. VI. and VII. of Botany*.

The first thirteen are of the plants which have *hermaphrodite* flowers, with the organs of *fructification* disjunct, no where cohering with one another, and observing no exact proportion in length.

The first is the *monandra*, containing two orders: the word is derived from the Greek *monos* and *andros*, one male part, and signifies a flower that has only one such.

This class accordingly comprehends those plants which have an *hermaphrodite* flower, and in it only one single *stamen* of this class are the *bitum*, *camus*, &c.

The second is the *diandra*, containing three orders; the word, derived from the same *dis* and *andros*, twice, and signifying a flower that has two male parts, comprehends all those plants which have *hermaphrodite* flower with two *stamina* in each: of this class are the *manaria*, *anthanthum*, *piper*, &c.

The third is the *triandra*, containing three orders; the word derived from the same *dis* and *andros*, three, signifies a flower that has three male parts in it, and comprehends those plants which have *hermaphrodite* flowers with three *stamina* in each: of this class are the *crucis*, *avena*, *molis*, &c.

The fourth is the *tetrandria*, containing four orders; the word, derived from the same *dis* and *andros*, four, signifies a flower that has four male parts in it, and comprehends those plants which have *hermaphrodite* flowers with four *stamina* in each: of this class are the *crucis*, *avena*, *molis*, &c.

and

word, derived from the same *ἀνδρ* and *τετρας*, four times, signifies a flower that has four male parts, and accordingly comprehends those plants which have hermaphrodite flowers, with four *filamina* in each: of this class are the *displanis*, *hammaridis*, *pyramides*, &c.

The fifth is the *pentandria*, containing five orders: the word, derived from the same *πεν* and *ανδρ*, five, signifies a flower with five male parts; and accordingly this class comprehends those plants which have hermaphrodite flowers with five *filamina* in each: of this class are the *verruca*, *anathum*, *lunaria*, *parafolia*, *causilla*, *myrsin*, &c. The sixth is the *hexandria*, containing five orders: the word, derived from the same *ανδρ* and *εξ*, signifies a flower that has six male parts, and accordingly comprehends those plants which have hermaphrodite flowers with six *filamina* in each; these *filamina*, the author observes, are either all equal in length, or alternately one shorter than another; the latter belong to the fifteenth class: of this class are the *amarilis*, *eryca*, *ranunc*, *patris*, *alifma*, &c.

The seventh is the *heptandria*, containing four orders: the word, derived from the same *ανδρ* and *επτα*, seven, signifies a flower with seven male parts, and comprehends those plants which have hermaphrodite flowers with seven *filamina* in the same flower with the pistillum: of this class are the *ajaculus*, *faros*, &c.

The eighth is the *octandria*, containing four orders: the word, derived from the same *ανδρ* and *οκτα*, eight, signifies a flower with eight male parts, and comprehends those plants which have hermaphrodite flowers with eight *filamina* in the same flower with the pistillum: of this class are the *amuretha*, *galenia*, *polygala*, *adax*, &c.

The ninth class is the *enandria*, containing three orders: the word, derived from the same *ανδρ* and *εννα*, nine, signifies a flower that has nine male parts, and comprehends those plants which have hermaphrodite flowers with nine *filamina* in each: of this class are the *zuffia*, *rhenu*, *botan*, &c.

The tenth class is the *decandria*, containing five orders: the word, derived from the same *ανδρ* and *δεκα*, ten, signifies a flower which has ten male parts, and comprehends all those plants which have hermaphrodite flowers with ten *filamina* in each: of this class are the *kamia*, *farisaga*, *stalaria*, *exalt*, *phys*, *lucia*, &c.

The eleventh is the *duodecandria*, containing five orders: the word, derived from the same *ανδρ* and *δωδεκα*, twelve, signifies a flower which has twelve male parts in it, and comprehends those plants which have hermaphrodite flowers with from twelve to nineteen *filamina* in the hermaphrodite flower: of this class are the *clavus*, *agrimonia*, *euphorbia*, *imperiolum*, &c.

The twelfth is the *icteandria*, containing five orders: the word, derived from the same *ανδρ* and *ικτεος*, twenty, signifies strictly a flower with twenty male parts in it; the author, however, does not understand it in that strict sense, but using it as we frequently do words expressing large quantities, as indefinite and in an indeterminate sense, defines it to mean only a larger number of *filamina* than are expressed under any other of the distinctions; and comprehends under it, in this class, all those plants which have hermaphrodite flowers and commonly twenty *filamina*, often more, in each; those *filamina* also growing to the inner side of the cup of the flower, not to the receptacle of the future seeds: of this class is the *pauca*, *crataegus*, *serotus*, *pyrus*, *rubus*, &c.

The thirteenth is the *polyandria*, containing seven orders: the word, derived from the same *ανδρ* and *πολυς*, many, signifies, in an exact sense, no other than what he makes the *icteandria*, the title of the last class, express: these are, perhaps, the only two words in which his expression is deficient, the name he has given the classes not at all importing their particular difference from one another: this, however, he has very accurately done in the character which follows them; and comprehends under this class those plants which have hermaphrodite flowers with from twenty to a hundred *filamina* in each, but which grow in this to the receptacle of the future seed, not as in the other class to the inner side of the cup of the flower: of this class are the *forficaria*, *pauca*, *acutum*, *apulegia*, *fractis*, *ranunculus*, &c.

These are the classes this accurate distinguisher has established among the hermaphrodite flowers, whose *filamina* have no regular proportion of length, in regard to one another. To these he next subjoins two classes of such of them as have ever two of their *filamina* shorter than the rest.

The first of these (the fourteenth class of the general order) is the *diandria*, containing two orders: the word, derived from *δύ* and *ανδρ*, two, or efficacy, signifies with him such flowers as have two of their male parts of more efficacy than the rest; and in this class he accordingly comprehends all those plants which have

hermaphrodite flowers with four *filamina*, two of which are close together, longer, and of greater efficacy, in the great work of fecundating the seeds, than the rest: of this class are the *melittis*, *mentha*, &c.

The second of these (the fifteenth class in the general order) is the *terandria*, containing two orders: the word, derived from *τρεῖς* and *ανδρ*, signifies a flower with four of its male parts of more efficacy than the rest; and in this class he comprehends the plants with hermaphrodite flowers, having six *filamina*, four of which are longer than the rest, the two opposite flori: of this class are the *lanaria*, *cheranthus*, &c.

From these he proceeds to those hermaphrodite flowers whose *filamina* cohere either mutually along one another, in different manners, or with the pistillum of the flower: those coherences of the *filamina* he calls brotherhoods, or communities, and according to the different state of these, and their conjunction with the pistillum, he establishes five classes of them.

The first of these (the sixteenth in the general order) is the *monadelphia*, containing five orders: the word derived from *μῆς*, single, and *ἀδελφία*, brotherhood, or community, signifies with him a flower, whose *filamina*, by means of the filaments running in among one another, are all forced into one body, and under this class he comprehends those plants with hermaphrodite flowers, whose *filamina*, or male parts, are all bound together in one body: of this class are the *hermannia*, *geranium*, *pentageta*, *alea*, &c.

The second of these (the seventeenth class in the general order) is the *diadelphia*, containing four orders: the word, derived from *δύ* and *ἀδελφία*, signifies with him a flower whose *filamina* are, by the conjunction of their filaments, formed into two bodies; and under this class he comprehends those plants which have hermaphrodite flowers, the *filamina* of which are so clustered together into two bodies: of this are the *femaria*, *polygala*, *lathyrus*, &c.

The third of these (the eighteenth in the general order) is the *polyadelphia*, containing three orders: the word, derived from *πολυς* and *ἀδελφία*, signifies with him a flower whose male parts are clustered into three or more separate bodies; and in this he comprehends those plants with hermaphrodite flowers, whose *filamina*, by the conjunction of their filaments, are formed into three or more clusters: of this class are the *theodroma*, *citrus*, *hypericum*, &c.

The fourth of these classes (the nineteenth in the general order) is the *syngenesia*, containing six orders: the word derived from *σύν*, together, and *γενεσις*, generation, origin, or formation, signifies with him such flowers as have their male parts naturally formed into a single regular congeries; and accordingly he comprehends under this class such plants as have hermaphrodite flowers, the *filamina* of which, by the junction of their apices, are formed into a single, regular, cylindric body: of this class are the *leontodon*, *arabidanthum*, *heliopsis*, *calendula*, *chrysos*, *lelelia*, &c.

The fifth of these classes (the twentieth in the general order) is the *gynandria*, containing eight orders: the word, derived from *γυνή*, a woman, or female, and *ανδρ*, male, signifies with this author a conjunction of the male and female parts of a flower at their origin; and he accordingly comprehends under this class those plants which have hermaphrodite flowers, the *filamina*, or male parts of which grow to the pistillum, or female part of the flower, and not to the receptacle of the seeds: of this class are the *orchis*, *hyacinthum*, *pulsifera*, *aristida*, *erum*, &c.

Next after these he ranges those plants which have flowers not hermaphrodite, but regularly and distinctly male and female, as the sexes in animals are disposed; and after these such plants as have flowers irregularly of one, or the other, or something of both sexes.

Of these he establishes only three classes. The first of these (the twenty-first class in the general order) is the *monocla*, containing eleven orders: the word, derived from *μῆς* and *αἰς*, a habitatio, signifies with this author such plants as have their distinct flowers on the same individual; and he comprehends accordingly under it those plants which have the male and female flowers distinct in themselves, but placed on the same plant, or the different stalks from the same root: of this class are the *zanichella*, *tripseum*, *urtica*, *poribrium*, *juglans*, *pinus*, *monordia*, *andros*, &c.

The second of these (the twenty-second class in the general order) is the *dicla*, containing fourteen orders: the word, derived from the same *αἰς* and *δύ*, signifies with him plants which have their male and female flowers not on the same individual; and accordingly comprehends under it such plants as have distinct male and female flowers, on different plants of the same species, either of which, the male and female plants, as they are

hence

hence called, might have arisen from the same seed: of this class are the *laice, empyram, vilcam, immutis, tamus, populus, mercurialis, ligularis, mentifpermum, diffusis, junciperus, rufcus, alia, &c.*

The third of these (the twenty-third in the general method) is the *polygamia*, containing three orders: the word, derived from *αἰος*, many, and *γᾶμος*, marriage, signifies with this author plants which have a diversity of combinations, and many ways of *fructification*, in the same species; and accordingly he comprehends under this class those plants which have, in the same species, some flowers male, others female, each distinct and perfect in its kind; and others mixed or *hermaphrodite*, with the male and female organs of *fructification* both in each: of this class are the *veratrum, fraxinus, ficus, &c.*

After all these he places those plants whose flowers are either absolutely invisible, or scarce discernible by the eye: of these he makes only one, his twenty-fourth and last class, the *cryptogamia*: the word, derived from *κρυπτός*, hidden, or *concealed*, and *γᾶμος*, or marriage, signifies a set of plants, in which the *fructification* is concealed; and under this last class he comprehends those plants which either flower, as is generally supposed, within the fruit, or have the organs of their *fructification* so mingled as to elude our observation: of this class are the *ferri, musci, fungi, and muscivori*; e. g. *polypodium, hrysos, facus, and agaricus*.

These are the classes into which this author has regularly and accurately reduced the whole vegetable world; the characters of which are so expressive, and the parts they are founded upon so fixed and invariable in their nature and office, that there seems no reason hereafter to perplex the world with any new system.

As the classes are here all taken from the number, size, and disposition of the male parts of the flower, to the orders which make their subdivisions are, by this author, deduced from the differences of the female parts or *stigmata*, and as that is single, double, triple, and so on, they are on the same principles named *monogynia, digynia, trigynia, &c.*

It were to be wished indeed, that the characters of the different genera of these classes were as perfect and accurate as the classes themselves: this, however, was more than the work of one man; the author has fixed the general distinction, and led the way, and it is easy now for a much less genius to follow him.

FRUCTIFERÆ, in Botany. See **BOTANY**.

FRUGIVOROUS Birds, are such as feed on fruits; either wholly or in part.

The *frugivorous*, according to Mr. Willughby, are a species of terrestrial birds, some of which have crooked bills, and claws, yet are of gentle nature, and not rapacious. Such are the parrot kind: which, though sometimes carnivorous, yet feed likewise on fruit.

FRUIT, in its general sense, includes whatever the earth produces for the nourishment and support of animals; as herbs, grain, pulse, hay, corn, flax, and every thing expressed by the Latins under the name *fruges*.

In the civil law, they distinguish three kinds of *fruits*. *Fructus, naturæ*, which the earth produces spontaneously, and without any culture; as those of trees.

Fructus industriae, which, though natural, require some culture to perfect them. And

Fructus civilis, which are only *fruits* in the eye of law; as rents, salaries, wages, &c.

In the canon law, *fruits* include every thing whereof the revenue of a benefice consists; as glebe-land, tithes, rents, offerings, &c.

FRUIT, in Natural History, denotes the last production of a tree, or plant, for the propagation, or multiplication, of its kind; in which sense *fruit* includes all kinds of seeds, with their furniture, &c.

FRUIT, in Botany, is properly that part of a plant wherein the seed is contained; called by the Latins *fructus*, and by the Greeks *καρπός*.

The *fruit* in the Linnaean system is one of the parts of *fructification*, and is distinguished into three parts, viz. the *pericarpium, arbor, and receptacle, or receptaculum fructuum*.

FRUIT are sometimes dry, and sometimes soft and fleshy. *FRUIT* also implies an assemblage of seeds in a head; as in a tancredium, &c. and in the general, all kinds of seeds, or grains, whether naked, or inclosed in a cover, capsule, or pod; and whether hard, fleshy, skinny, membranous, or the like. The *fruit* is the product, or result, of the flower; or that for whose production, nutrition, &c. the flower is intended. The structure and parts of different *fruits* are somewhat different; but, in all the species, the essential parts of the *fruit* appear to be only continuations, or expansions, of those observed in the other parts of the tree.

Dr. Beal suggests some very good reasons for a direct

communication between the remotest part of the tree, and the *fruit*; so that the same fibres, or lamina, which constitute the root, trunk, and boughs, are extended into the *fruit* itself.

Thus, cutting open an apple transversely, it will be found to consist of four parts; viz. 1. a skin, or *coria*, which is only a production of the skin, or outer bark, of the tree. 2. A *parenchyma*, or pulp; which is an expansion, and intumescence of the inner bark of the tree. 3. Fibres, or ramifications, of the woody part of the tree, dispersed throughout the *parenchyma*.

Of these last, authors generally reckon fifteen principal branches; ten whereof penetrate the *parenchyma*, and incline to the basis of the flower; the other five ascend more perpendicularly from the pedicle, or stalk, and meet with the former at the base of the flower; to these branches are fastened the capsule, or coats, of the kernels.

These branches, being at first extended through the *parenchyma* to the flower, furnish the necessary matter for the vegetation thereof; but, the *fruit* increasing, intercepts the aliment; and thus the flower is starved, and falls off.

4. The core, which is the produce of the pith, or medulla, of the plant, indurated and strengthened by twigs of the wood and fibres, imbedded therewith: it serves to furnish a cell, or lodge, for the kernels; filtrates the juice of the *parenchyma*; and conveys it, thus prepared, to the kernel.

In a pear we distinguish five parts; viz. the skin, *parenchyma*, ramification, stone, and acetarium.

The three first parts are common to the apple. The stone, observed chiefly in chock pears, is a coagery of hard epidermis, dispersed throughout the whole *parenchyma*; but in the greatest plenty, and closest together, about the centre, or acetarium: it is formed of the harder, or calcareous parts, of the nutritious juice of the *parenchyma*, extravasated in masses. The acetarium is a substance of a tart, acid taste, of a globular figure, inclosed in an assemblage of several of the stony parts above mentioned. In the plum, cherry, &c. there are four parts; viz. a coat, *parenchyma*, ramification, and stone or nucleus. The stone consists of two very different parts; the inner, called the kernel, is soft, tender, and light; being derived from the pith, or medulla, of the tree, by seminal branches, which penetrate the base of the stone; the external or harder part, called the shell, is a concretion of the stony, or calcareous parts of the nutritious juice, like the stone in pears; and, like that, it contains a soft parenchymous matter within it.

The nut, analogous to which is the acorn, consists of a shell, cortex, and medulla. The shell consists of a coat, and *parenchyma*, derived from the bark, and wood, of the tree. The cortex consists of an inner, and outer part; the first is a duplicature of the inner tunic of the shell; the second is a mossy substance, derived from the same source as the *parenchyma* of the shell. But whether the medulla or pulp of the kernel arise from the pith of the tree, or the cortical part of the fruit, is not yet agreed.

Lastly, berries, as grapes, &c. besides the three general parts, viz. coat, *parenchyma*, and ramification, contain grains of a stony nature, which do the office of seeds.

As to the use of *fruits*, beside the pleasure and advantage they afford men, &c. they are of service in guarding, preserving, and feeding the seed inclosed; in filtrating the coarser, more earthy, and stony parts of the nutritious juice of the plant, and retaining them to themselves; and sending none to the seed but the purest, most elaborated, and spirituous parts, for the support and growth of the tender, delicate embryo, or plantule, contained therein.

So that the *fruit* does the same office to the seed, that the leaves of the flower do to the fruit.

The use of *fruits* with us might, under proper regulations, be rendered much more extensive than it is. Many *fruits* which do hurt when eaten raw, would make wines equal in flavour to many of those now obtained at great prices from abroad; and lands which will not bear corn, yet would bear trees and shrubs producing such *fruits*; and the consequence of this method of culture would be, that much ground, at present lying waste, would be occupied, and great employment found for the numerous poor of some of our counties, where the quantities of waste land are proportionably so great, that there is not employment for the people of one half of the county. Cherries properly managed make an excellent wine, and that in very large quantities; and plums also make a very agreeable kind; but that it has an astringency, which must be taken off by mixing a little sugar with it when in the glass, not before it is drawn off.

A coarse plum, somewhat larger than a damson, is the best

best kind for this wine. There is a sort of plum that grows wild in some of our hedges. It will succeed on any ground, the poorest that can be imagined, and it produces a great abundance of fruit. The wine that is made from it is of a very considerable strength, and affords a pleasant brandy by distillation in considerable quantities. Our common garden currants afford a very agreeable wine; and our gooseberries are not second to any thing. All these produce fruit in great abundance; and the planting and taking care of them is very cheap, and the operation very easy. The common way of making these wines yields very good ones; but when the art of the experienced Vignerons is employed in it, the liquors will prove much better. Phil. Trans. N° 124.

Fruits are distinguished, by gardeners, into *stone-fruit*, and *kernel-fruit*; *summer-fruit*, and *winter-fruit*; *wall-fruit*, and *dwarf-fruit*, &c.

M. Quintinie observes, that cold, heavy, moist lands, produce the fairest and largest fruit; but the hotter, drier, and lighter, the more delicious and rich-tasted.

Fruits, colour from. The red juices of fruits, as of currants, mulberries, elder-berries, morcello, and black cherries, when inspissated and dried, may be again dissolved in water, to which they give nearly the same red colour as they do when fresh. Rectified spirit extracts the tinging particles, and acquires a brighter colour than the watery solution; because much of the mucilage is left undissolved by the former. The red solutions, and the juices, are sometimes made dull, and sometimes more florid, by acids, and are generally rendered purplish by alkalis. The colours of these juices are generally perishable. They resist the power of fermentation, but quickly decay, when the juice is spread thinly on any substance, and dried in open air. The bright lively reds are soon changed; the dark, dull, red stain of the black cherry is considerably durable. The bright red fruit of the *spinaria*, or prickly pear, is an exception to the above rule; as it gives, according to Labat, a beautiful red dye. The ripe berries of *BUCKTHORN* stain paper of a green colour; from these is prepared the substance called *sax-green*, which is a pigment sufficiently durable, soluble in water, but not miscible with oil. The berries, when green, yield a yellow, and, when over-ripe, a purple pigment. Woollen cloth, prepared with alum and tartar, receives, on being boiled with the berries, a perishable yellow dye. Neumann's Chem. with Dr. Lewis's Notes, p. 433. See *AVIGNON BERRY*, *ANNOTTO*, or *ROUCOU*, and *TURNESOL*.

Fruits, preservation of. See *Preservation of Flowers*, and *PRESERVATION OF VEGETABLES*.

Fruits intended for long keeping should be gathered before they are fully ripe, and in a fair day towards noon. For the early ripening of fruit, see *FORCING* and *RIPENING*.

Fruit, bread. See *BREAD*.

Fruits, with regard to commerce, are distinguished into *exotic* or *foreign*, and *domestic*.

Fruits, recent, are those sold just as they are gathered from the tree, without any farther preparation. As are most of the productions of our gardens and orchards, sold by the fruiterers.

Fruits, dry, are those dried in the sun, or by the fire, with other ingredients sometimes added to them to make them keep; imported chiefly from beyond sea, and sold by the grocers.

Such are raisins, currants, figs, capers, olives, cloves, nutmegs, pepper, and other spices; which see under their respective articles.

Under the denomination of *dry fruits* are also frequently included apples, pears, almonds, filberts, &c.

Fruits, polytypous. See *POLYTYPEOUS*.

Fruits, current for coins. See *COIN*.

Fruit, fish. See *FISH*, *fruit*, *ANNATES*, and *PRIMITIV*.

Fruit-fly, a name given by gardeners, and others, to a sort of small black fly, found in vast numbers among fruit-trees, in the spring-season, and supposed to do great injury to them.

These are a species of small black fly. Mr. Leeuwenhoek preferred some of them for his microscopical observations. He found that they did not live longer than a day or two, but that the females in this time usually laid a great number of longish eggs. The gardeners who suppose that these flies wound the leaves of the trees, are mistaken: 'tis true that they feed on their juices, but they have no weapons with which to extract this themselves; they feed on such as is naturally extravasated, and when there is not enough of this for their purpose, they haunt those places where the *PUCERONS* resort, and feed on the juices which these little creatures extravasate by means of the holes they bore in the leaves with their trunks. These pucerons are a small sort of insect very common

VOL. II. N° 143.

on our fruit-trees, and other plants and trees; they are of a greenish colour, and are commonly called tree-lice. Phil. Trans. N° 262.

Fruit-stone. The mischief arising from the bad culum of many people swallowing the stones of plums and other fruit are very great. The Philosophical Transactions give us an account of a woman who suffered violent pains in her bowels for thirty years, returning once in a month or less. At length a strong purge being given her, the occasion of all these complaints was driven down from her bowels to the anus, where it gave a sensation of stoppage and distension, and produced a continual desire of going to stool, but without voiding any thing. On the assistance of a careful hand in this case, there was taken out with a forceps an oblong ball of an oval figure, of about ten drams weight, and measuring five inches in circumference; this had caused all the violent fits of pain she had been for many years afflicted with, and after the taking it out she became perfectly well. The ball extracted looked like a stone, and felt very hard, but it swam in water on cutting it through with a knife, there was found in the centre of it a plum-stone, round which several coats of this tough and hard matter, resembling a stone, had gathered. Another instance given in the same papers is of a man, who dying of an incurable colic, which had tormented him many years, and baffled the effects of medicines, was opened after death; and in his bowels was found the cause of his distemper, which was a ball of the like nature with that just mentioned, but something larger, being six inches in circumference when measured, and weighing an ounce and half; in the centre of this, as of the other, there was found the stone of a common plum, and the coats were of the same matter with those of the former. These and several other instances mentioned in the same place, sufficiently shew the folly of that common opinion, that the stones of fruits are wholesome.

For though by nature the guts are so defended by their proper mucus, that people very seldom suffer by things of this kind, yet if we consider the various circumpulations of the guts, their valves and cells, and at the same time consider the hair of the skins of animals we feed on, the wool or down on herbs and fruits, and the fibres, vessels, and nerves of plants, which are not altered by the stomach, it will appear a wonder that instances of this sort of mischief are not much more frequent. Cherry stones, swallowed in great quantities, have occasioned the death of many people, and there have been instances even of the seeds of strawberries, and kernels of nuts, collected into a lump in the guts, and causing violent disorders, which could never be cured till they were carried off. Philol. Trans. N° 282. p. 1281.

Fruit-trees are distinguished, like the *fruit* they bear, into *wall-fruit-trees*, *standard fruit-trees*, &c.

With regard to *fruit-trees*, Mons. Quintinie observes, 1. That the cutting and trimming of young trees hinders them from quick bearing; though it contributes both to the beauty of the tree, and to the richness and flavour of the fruit.

2. That kernel *fruit-trees* come later to bear than stone *fruit-trees*; the term required by the first, before they arrive at a fit age for bearing, being, one with another, about four or five years; but, when they do begin, they bear in greater plenty than stone-fruit.

3. That stone-fruit, figs, and grapes, commonly bear considerably in three or four years; and bear full crops the fifth and sixth years; and hold it for many years, if well ordered.

4. That *fruit*, in the same neighbourhood, will ripen a fortnight sooner in some grounds, than in others of a different temperature.

5. That in the same country, hot or cold summers set considerably forwards or put backwards, the *fruit* fruit.

6. That the *fruit* of wall-trees generally ripen before those on standards; and those on standards before those on dwarfs.

7. That the *fruit* of all wall-trees, planted in the south and east quarters, commonly ripen about the same time; only those in the south rather earlier than those in the east; those in the west are later by eight or ten days; and those in the north by fifteen or twenty.

For the planting, pruning, engraving, &c. of *fruit-trees*, see *PLANTING*, *TRANSPLANTING*, *PRUNING*, and *ENGRAFTING*. See also *ORCHARD*, *GARDEN*, and *NURSERY*.

Mons. de Reffons, in the Mémoires de l'Académie Royale des Sciences, ann. 1716, gives us a method of grafting stone *fruit-trees* without losing of time; so that a tree which bore bad *fruit* the preceding year, shall bear the choicest *fruit* the year following.

It frequently happens that persons are deceived in their *fruit-trees*, especially those bought of the nursery-men; and

and it is an unpleasant thing, after having waited three years for *fruit*, to find it bad at last, and to be obliged to graft the tree again, and wait four years more for the second hopes. In effect, in the common methods of grafting, they know nothing better than to cut off the head of a tree, and make it put forth new wood to graft in: this necessarily makes a long delay, which Monf. Reaumur shows how to abridge.

Upon considering the union of the sap in grafts, that author was led to think, that all the office the bark has in grafting, is to receive the cutcheon; so that if the bark be not quite hard, dry, and inflexible, and incapable of yielding without cracking or bursting, it should seem indifferent, whether one grafted on new wood, or old, the sap passing equally into both: which reasoning had the good fortune to be verified by a number of experiments made with that view.

We are at liberty, then, to graft almost at any age, and in any wood. Accordingly, a peach tree of a worse kind or quality may be grafted from another of the best, in autumn, in the height of its *fruit* and sap, without cutting off any branches; the graft soon cements to the tree by the union of the sap, without shooting at all: so that, cutting off the branches above the grafts the spring following, the same graft inserted the preceding autumn will shoot vigorously; and, being on a wood of the same kind, the *fruit* themselves produced will be much the larger and finer. But this is not the great point: for the tree thus engrafted will not bear till the third year, and we want *fruit* the first.

In order to this it is to be observed, that there are three kinds of branches: wood-branches, growing immediately from the stem or stock of the tree; *fruit*-branches; and branches half of the wood, half of the *fruit* kind, being such as, arising from the largest wood-branches, prefigure the character thereof, but which, in two years time, will produce *fruit*-branches. Now, this intermediate kind of branches should be chosen for cutcheons or grafts. They are easily known by being bigger than the *fruit*-branches, and less than the wood-branches: they have each of them two, three, four, or even five leaves to each eye; and the eyes are farther distant from each other than those of the *fruit*-branches, but closer than those of the wood-branches. It must be added, that the eyes on such branches are three; one intended for a wood-branch, being situate between the two leaves, and advancing farther than the other two, which are intended for *fruit*, and are placed without-side the leaves.

These last are the precise subjects to be chosen for the purpose of grafting. Twelve of these cutcheons, more or less, according to the strength of the tree to be grafted on, being duly applied, we may depend on a crop of good *fruit* the very next year, on the same tree which the last year produced the wood.

There is, in the Philosophical Transactions, a method of making *fruits* and flowers grow in winter instead of summer, without the common way of doing it by heat. This method is to take up the trees with their roots in the spring-season, just as they begin to shoot out their buds; let them be placed upright in a cellar, and stand there till the end of September following; then fit vessels to them, and place the roots in them, covering them in a proper manner with earth, and bring them up into a common floor; water them at times with a solution of the bigness of a walnut of crude salt ammoniac in a quart of rain-water, and they will make their natural progress as in summer, and in the months of February or March following the *fruit* will be full ripe, and as well tasted as if it had grown on them in the common way, and ripened at its natural season. Phil. Trans. N° 282. p. 44. The superfluous shoots from these trees must be pruned off at such times of the year, when the trees are full of juice, and furnished for a farther supply; and by this means there will be no marks of the wounds, they will close up perfectly. The manner of producing pyramidal trees by ingrafting, is not only applicable to *fruit*-trees, but has been tried on oaks, limes, and roses, with the same success. Vide infra.

Laurebergius tells us of a peculiar way of managing *fruit*-trees for ready service and beauty, by means of which they will bear *fruit* the first year. The method is this: draw a branch of a *fruit*-tree through a pot of earth, and prick it full of holes with a knife, so far as it is to stand in the pot: let it be well watered for the first seven or eight days, to make it shoot out a great quantity of roots; in the March following cut off the branch from the tree, and let it depend wholly on itself for nourishment; break the pot away, and place the clump of earth with the young tree in it in the place where it is intended to stand. The author assures us it will partake so much of the nature of the stock, as to bear *fruit* the first year. Philol. Trans. N° 3.

An anonymous author has given us, in a treatise published at Hamburg, under the title *Amplius Hortensis Nova*, a new method of grafting trees, so as to have very beautiful pyramids of *fruit* on them, which will exceed both in quantity, beauty, and flavour, all that can be otherwise produced. This, he says, he had long experienced, and the method he gives of doing it is this: the trees are to be transplanted in autumn, and all the branches cut off; early in the following summer the young shoots are to be pulled off; and the buds are then to be ingrafted into them in an inverted direction; this, he says, adds not only to the beauty of the pyramid, but makes the branches also more fruitful. These are to be closely connected to the trunk, and to be lashed in with the common ligature; they are to be placed circularly round the tree, three buds in each circle, and these circles at six inches distance from one another. The old trees may be ingrafted in this manner, the cutcheons having been found very good in those of twenty years standing; but the most eligible trees are those which are young, vigorous, and full of juice, and have not more thickness than a finger or two. When these young trees are transplanted, they must be fenced round with pales, to defend them from the violence of the winds; and there must be no dung put to them till they are thoroughly rooted, for fear of rotting them before the fibres strike. The buds ingrafted must be small, that the wounds made in the bark to receive them, not being too large, may heal the sooner; and if any of the buds do not succeed, which will be found in a fortnight, there must be others put in their place. The wound made to receive these buds, must be a straight cut, parallel to the horizon, and the piece of bark taken out must be downward, that the rain may not get in at the wound. In the autumn of the same year, this will be a green and flourishing pyramid, and the next summer it will flower, and ripen its *fruit* in autumn. Act. Acad. ann. 1710.

The Petersburg Academy furnishes us with two very singular instances of *fruit* growing in an unnatural manner; the one of those in the fig-tree, the other in the apple-tree. In both those cases, the *fruit*, instead of its common situation, was placed upon the trunk of the tree, with no branch or leaf near it, but only a short pedicle for its support. The instance of the fig-tree afforded three figs in a cluster, the middle one of which withered, but the other two grew to their proper size, and were like the rest of the figs on the same tree. The other instance of the apple-tree afforded only one single *fruit*; but there was in it something very strange, or that appeared so, however, at first sight, for the apples produced on the branches of the tree were of one kind, and this of another. The tree had been grafted, and all the *fruit* of the branches grew from the graft; this single one, which stood upon the trunk of the tree below the graft, was of the species produced by the stock. This had doubtless been preceded by a flower, though unobserved, and it could only be, as it appeared, of the nature of the genuine *fruit* of the stock. All gardeners know, that the stock suffers no change from the graft; in both these cases there was probably the rudiment of a branch where the single *fruit* appeared, and every other part of it, except the bud of the *fruit* alone, had perished, while that arrived at its destined size and maturity. We have also an account in the Philosophical Transactions, N° 385, of an apple-tree bearing a considerable quantity of *fruit* for many years together without blossoming.

FRUITERY, a place for the lying up and keeping of FRUIT. See GRANARY.

The *fruitery* should be inaccessible to any thing of moisture, or even frost.

FRUITFULNESS, the quality of bearing plenty of fruit, called also FERTILITY, and FECUNDITY.

FRUMENTACEOUS plants are those which produce geniculated or knotted stalks, with reed-like leaves; and whose seed growing in spikes or *spikes*, is useful to make pulque, or bread.

The word is formed from *frumentum*, a general name comprehending all sorts of corn, or grain, for bread. Hence the Italians, who follow the Latins, use *grano* and *frumento* for the same.

Wheat, barley, rye, millet, &c. are *frumentaceous* plants. Some authors use *frumentaceous* in a narrower sense, restraining it to plants which bear a conformity to wheat, either in respect of their frusca, leaves, ears, or the like. But this seems founded on a mistaken notion of *frumentum*, as if it denoted only wheat, which is rather the sense of the word *triticeum*.

FRUMENTARI, in *Antiquity*, a kind of soldiers, or archers, under the Western empire.

St. Cyprian relates, in one of his letters, that some of these *frumentarii* were sent to take him.

The first time we read of *frumentarii*, as officers, is in the

the time of the emperor Adrian. Spartian, in his life of that prince, assures us, that he made use of them to inform himself of what passed.

Before this time, the name *frumentarius* was only given to the corn-merchants, or measurers of corn.

The *frumentarii* did not make any particular corps, distinct from the other forces, but there was a certain number of them in each legion, as, among us, there is a certain number of grenadiers in each battalion. Accordingly, in ancient inscriptions, we meet with *frumentarii* of this or that legion. It is supposed they were originally a number of young persons, disposed by Augustus throughout the provinces, particularly on all the grand roads to advertise the emperor, with all expedition, of every thing that happened.

In order to this they had a kind of intendants of all the carriages, and on this account came to be employed for the conveyance of corn, *frumentum*, to the armies; whence their appellation.

Afterwards they were incorporated into the troops themselves, where they still retain their ancient name.

Their principal office was the giving intelligence, in which they agreed with those called *curiosi*, with whom they were frequently joined. See *Curiosi*.

FRUMENTATION, *frumentation*, among the Romans, a largess of corn bestowed on the people. This practice of giving corn to the people, was a very ancient custom among the Romans, and frequently used to soothe the turbulent humour of the populace.

At first the number of tho' to whom this largess was given, was indeterminate, till Augustus fixed it at two hundred thousand.

FRUMENTUM Saracenicum, in *Batany*, a name by which some authors express the sagopyrum, or *barley-wheat*.

FRUMENTUM Indicum, *Indian corn*, a name given by our American planters to MAIZE.

FRUMENTY, popularly *FURMETY*, a kind of porridge, the basis whereof is wheat, boiled up with milk, sugar, and sometimes spice.

Pliny tells us, that in his time they mixed chalk among it. Galen describes it as a very nutritious food made of corn, or pulse, boiled with water, wine, and oil.

The Latins called it *altia*, which Festus derives *ab altendo*, as being very nourishing. But then it must be observed, they made it of any kind of corn.

Ours being restrained to wheat, we have given its denomination accordingly, from *frumentum*. An emulsion, wherein wheat was an ingredient, would be a kind of *frumenty*.

FRUMGYLD, in our old Writers, is the first payment made to the kindred of a person slain, towards the recompence of his murder.

FRUMSTOL, in our old Writers, the chief seat or mansion-house, which is called by some the *hymstal*. Leg. Int. cap. 38.

FRUSO, in *Zoology*, a name given by some to the *ecce-thraustes cristata Indica*, commonly called the *Virginian NIGHTINGALE*.

FRUSSURA, in our old Writers, a breaking down; also a ploughing or breaking up. *Frassura domorum* is house-breaking; and *frassura terræ*, new broke land.

The word comes from the French, *frassure*, a bruise; and that from the verb *frasser*, to bruise or break.

FRUSH, or *FRON*, in the *Monges*, is a sort of tender horn which arises in the middle of the sole, and at some distance from the toe of a horse; it divides into two branches, running towards the heel, in form of a fork.

FRUSTUM, in *Mathematics*, a piece cut off or separated from a body.

FRUSTUM of a pyramid, or cone, is a part or piece thereof cut off, usually by a plane parallel to the base.

All round and square timber that grows tapering, may be conceived as the *frustum* of a cone, or pyramid: to find the quantity whereof, take the following theorem, which in the main is Mr. Oughtred's. Given, B (*Tab. Survey*, fig. 10.) the side of the greater base, b the lesser base's side, A the height of the *frustum*: though, below, we suppose B and b to represent the areas of the two bases. Whole height $\frac{A}{2} + H = H$.

First, to find $\frac{A}{2}$, say, as $B - b : b : A : \frac{b}{B - b}$ or $\frac{b}{A}$.

Now $BH = 3$ times the whole pyramid, because any prism is three times a pyramid of the same base and height whith, by 7 and 10 Euclid, and $bA = 3$ times the upper pyramid.

Wherefore $\frac{BH - bA}{3}$ equal to the *frustum* of the pyramid required; which theorem in words is this:

Multiply the lower base by the whole height, and from the product subtract the upper base multiplied by the

height of the top-piece wanting, and then one third of the remainder shall give the *frustum*.

And in the same way you may proceed for the *frustum* of a cone; only it will be more difficult to find the circular bases. See *CONE*.

FRUSTUM of a sphere. See *SEGMENT*.

We have a general theorem in Mr. Maclaurin's Treatise of Fluxions, concerning the *frustum* of a sphere, cone, spheroid, or conoid, terminated by parallel planes, when compared with a cylinder of the same altitude, on a base equal to the middle section of the *frustum* made by a parallel plane. The difference between the *frustum* and the cylinder is always the same in different parts of the same, or of similar solids, when the inclination of the planes to the axis, and the altitude of the *frustum*, are given.

In the parabolic conoid this difference vanishes, the *frustum* being always equal to a cylinder of the same height, upon the section of the conoid that bisects the altitude of the *frustum*, and is parallel to its bases.

In a sphere the *frustum* is always less than the cylinder by one fourth part of a right angled cone, of the same height with the *frustum*, or by one half of a sphere of a diameter equal to that height; and this difference is always the same in all spheres, when the altitude of the *frustum* is given.

In the cone, the *frustum* always exceeds the cylinder by one fourth part of the content of a similar cone that has the same height with the *frustum*.

In the hyperbolic conoid this excess is the same as in the cone generated by a triangle aca , (*Tab. II. Geometry*, fig. 44.) formed by the axis ac , the asymptote cc , and a perpendicular ca , the altitude of the *frustum* and the inclination of the axis to their bases being the same in both.

In the spheroid (fig. 45) the cylinder exceeds the *frustum*; and the difference between them is the same as in the cone $C D r d$, the plane $D r d$, or $B b b$, being supposed parallel to those which terminate the *frustum*.

In different inclinations of those planes, when the altitude of the *frustum* is given, that difference is reciprocally as the cube of the diameter Bb , which is the conjugate of CA , the axis of the *frustum*. But if the altitude of the *frustum* be also varied so as to be reciprocally proportional to the diameter Bb , then the difference between the *frustum* and cylinder will be always of the same magnitude in the same spheroid or conoid.

When the inclination of the axis of the solid to the planes that terminate the *frustum* is given, the difference between the *frustum* and cylinder, in the same, or in similar bodies, is as the cube of their common altitude. Maclaurin's Fluxions, Introd. p. 24, 25.

These propositions concerning *frustums* are of use in GAUGING.

FRUTEX. See *SHRUB*.

FRUTEX Ethiopicus, in *Batany*, a name given to the silver *PINE-tree*.

FRUTEX Africana, in *Batany*, a name given to a species of trees brought from the Cape of Good Hope; a description of which see under *Spurge-leaved PINE*.

FRUTICOSE *stems of plants* are those of a hard, woody substance.

FRY, in *Ichthyology*, signifies the spawn, or rather the young of fish. See *FISH*.

FRYTH, or *FRITH*, is explained, by Sir Edward Coke, as a plain between two woods, or a lawn.

Camden ties it for an arm of the sea, or a straight between two lands, from *frutum*.

Frith, from the Saxon *frid*, peace, is also used for a wood; because the English Saxons held woods to be sacred, and used them as sanctuaries.

FUAGE, or *FORAGE*, a tax or imposition laid on hearths or chimneys, i. e. on fire-places, or families, from which was probably derived the *hearth-money*, and *chimney-money*. This duty was repealed by 1 William and Mary, sect. 1. cap. 10.

Edward the Black Prince, having Aquitain granted him, laid an imposition of *fuage*, or *forage*, upon the subjects of that dukedom, viz. one shilling for every fire-place. After his example, Charles V. of France, laid a tax of a franc for each fire-place, for one year only. His successor Charles VI. augmented it under the same name. Charles VII. rendered it perpetual, and called it *taille*. By an ordinance of Humbert II. dauphin of Viennois, the imposition of *fuage*, or *forage*, was then laid per feu, i. e. per fire, or family, *in per lares forum habentes*. In Latin it was called *foagium*, q. d. *pro singulis focis*. Sometimes it was also called *fourage*, on account of the oven or furnace: in Greek *καυνοει* or *καυνοει*, *καυνοει*, *καυνοει*. In Will. Tyr. De Bello Sacro, it is called *foagium*: for it was imposed by the kings of Jerusalem, The counts and other lords, likewise imposed it on the feudataries,

foodstuffs, or radials. Zonars affirms us, that the general Nicophorus first established it among the Greeks. See CHIMNEY-money.

FUCA, in *Ichthyology*, a name given by Gaza, and some other writers, to the fish called phycis, by Aristotle, Elian, and other writers; and *trina marina*, by Salvin and Rondeletius. It is a fish nearly allied to the genus of the Menni.

FUCHSIA, in *Botany*, the name of a genus of plants of the *strobilacea* class; so called by Plummer, in memory of the famous Botanist Fuchsius, Plum. Nov. Gen. 14. the characters of which are these: the flower hath one petal with a closed tube, slightly cut into eight parts at the bein; and hath four stamina the length of the tube. An oval germen is situated under the flower, which afterwards becomes a fuculent berry with four furrows, having four cells, containing several small oval seeds. There is one species, a native of the warm parts of America.

FUCUS is used for a paint, or composition, applied on the face, to beautify it, and heighten the complexion.

Old women make use of *fucus* and pomatums, to appear young. The *fucus* made with *cerusi* is corrosive and pernicious to the skin.

Pliny says, that the *fucus* of the Roman dames was a kind of white earth, or chalk, brought from Chio and Samos, dissolved in water.

The *fucus Solimanii* is a composition of prepared sublimate, in great repute among the Spaniards of Peru.

FUCUS Giganteus, a name given by Mr. Banks and Dr. Solander to a kind of sea-weed of an enormous size, which they discovered in their passage from Rio de Janeiro to the Straits of Le Maire. The leaves of it were four feet long, and some of the stalk, though not thicker than a man's thumb, above one hundred and twenty.

FUCUS, in *Botany*, the name of a genus of submarine plants of the class of *cryptogamia* and order of *algæ*; the characters of which are, that they are of a tough structure, and formed into a kind of leaves, which are flat, and variously diversified. The male flowers are vesicles interwoven with small fibres, and the female are vesicles interspersed with small prominences; they have a single seed. See Tab. VII. of *Botany*, Class 24. N. 3.

The species of *fucus* enumerated by Mr. Tournefort are seventy-seven; and by Linnaeus are fifty-two.

Mr. Reaumur has discovered, that all the *fuculi* produce regular flowers and seeds, in the same regular manner. The flowers stand all over the leaves from the origin of them at the root to the utmost extremities, only the ribs in the middle are free from them. Every flower is composed of a cluster of small and extremely slender threads.

These are usually all of the same length in the same flower, but they are so numerous as not to be easily counted; the longest of these threads are not above one twelfth of an inch in length, and the rest are not half so long.

They all issue out of a small hole in the leaf, which serves as a sort of cup to them. The threads are too feeble to support their own weight in the air. When the sea has left the plants, they are all found lying flat upon the leaves; though while the water covers them, they stand somewhat erect.

They are not terminated at the top by apices containing a farina; but they may very easily contain that powder in their whole substance, and throw it off as soon as they expand themselves. They are disposed with no sort of regularity on the leaves; for in some places they stand very close together, in others they are placed at much greater distances. They grow equally on both sides of the leaves; but the same flower never perforates the leaf, but all its parts appear on the same side.

The flowers are much more easily discerned on the plant when it is dry, than while it is moist; for when dry, the filaments that compose them are white; whereas when moist, they are of a deep brown, like the leaves on which they stand.

All the flowers which cover these plants, there are none that produce seeds but those which are placed near the extremities of the leaves, and not all of these. In those places where the seed is beginning to form itself, the extremity of the leaf swells, and forms a sort of capsule, which contains the fruit, while the rest of the leaf retains its former thinness.

When the flowers are fallen, the holes in the leaf which served them for cups, become easily visible in the places where the thickets happen, and where the seeds are to be lodged; and the margin of each hole is surrounded with a little circular protuberance, which stands out beyond the rest of the surface.

The swelled ends of the leaves grow often to half an inch in thickness, and usually terminate in two horns, which form an acute angle; and the rib of the leaf is not visible in these swollen parts. When these are cut open, whether it be transversely or horizontally, they are found filled with a thick viscid liquor, and in this are seen several roundish bodies of about a twentieth part of an inch in length; they

are of a reddish colour, and are easily distinguished, and are all found to be fixed to the side of the leaf. These are what Dr. Robinson, who seems to have been the first person who discovered them, took for the seeds; and they have really much the appearance of naked seeds; but, when closely examined, they are found to be really capsules containing each a great number of minute round seeds, which are fastened to their sides, as they were to the sides of the tumor in the leaf; and these smaller capsules are in the same manner with those full of a transparent viscid liquor.

Though these capsules appear at first sight plain roundish bodies; yet when more nearly examined, they are found to be rather shaped like glass bottles with short necks, the neck being fixed into the substance of the leaf, and its extremity forming the protuberant circular rim that surrounds the little hole in the leaf, which had served as a cup to the flowers. See Mem. Acad. Par. 1711, where we have figures of the *fucus*.

Fucus palmatus, banded *fucus*, the name given to a species of sea *fucus*, distinguished from the rest by its having no stalk, its leaves being divided in the manner of a hand, and its extremities divided into many curled segments. It is common on almost all the sea coasts of Europe, and is one of the several species of sea plants in which Mr. Reaumur has discovered regular flowers and seeds. They are in this species however so small, as to require the assistance of a microscope to discover them; though after they have been once seen in that manner as is the case in many microscopic objects, they may then be easily distinguished by the naked eye. This plant is fastened to some stone by a round root, from which there arise four or five leaves, which at about an inch distance from the root divide into a number of branchings, which constitute the whole plant. This species carries its seeds at the extremities of the leaves, where they are inclosed in the interior substance of the plant; and nothing is to be discovered on the surface without the assistance of glasses, unless it be that the leaves are of a somewhat more dusky hue than elsewhere, which is caused by a number of small opaque bodies; and when this obscure part of the plant is opened, there appear a number of small, round, and hard reddish seeds, which may, probably, be capsules or seed-vesicles, and not single seeds.

Fucus polychides. See *POLYCHIDES*.

Fucus thermalis, in *Botany*, the name of a remarkable species of plant, found only in the hot-water springs. It was first discovered by Mont. de Monteleuque, in the great basin, at the boiling spring in Gascogne; he was not able to discover that it produced either flowers or seeds. Its substance is entirely composed of small bladders full of air, the surfaces of which are reticular, as worked in the manner of coarse canvas. It is observed to grow only in the hottest waters.

FUDDER, among the *Miners*, a load of lead, which is eight pigs, or sixteen hundred weight.

FUEL, in *Philosophy*, the *paladium* of FIRE, or whatever receives and retains fire, and is consumed, or rendered insensible thereby.

A great deal of nicety is required in choosing the proper fuel to raise and continue the several degrees of fire, in chemical operations. The natural heat of the summer sun is sufficient for insulations. A spirit-lamp may be made to give the next degree of heat to this, which may be much augmented or decreased, according to the number of wicks kept burning at a time.

The next degree of fire to this, is made of the lighter fuels, such as dry straw, leaves, twigs, and the like; the next in order, is that from oils, wax, resin, pitch, &c. And lastly, solid wood, coals, and turf, may be employed for the strongest. These, by means of proper furnaces made to contain different quantities, may be made to give a greater or less degree of a strong fire. To excite the greatest degree of heat in a furnace, the rule is to use the densest fuel, and in the largest quantity, and to have bellows placed all round the furnace: these are to be incessantly blown, and directed to the central part of the fire, in which the matter to be worked upon is lodged. Thus the greatest degree of heat from culinary fire is to be given, and this is sufficient for the known operations on metals, glass, &c.

It is a known truth, that fuel cannot consume by means of heat alone, without the admission of fresh air, and this is no way more clearly proved, than by this easy experiment. Let a strong cylinder of iron, hollow within, be fitted with a firm screw at each end; in the cavity of this cylinder inclose a long piece of charcoal, and then screw up both the ends fast, and place the whole in a strong fire; let it continue there for several hours; and when it is taken out and cooled, open it, and the piece of charcoal will be found still black, in its own form, and no way apparently altered or diminished.

It is plain from this, that the consumption of fuel depends

depends upon the rarefaction, dilodgment, brisk agitation, and discharge of its inflammable vapour, by means of fresh air; and hence we have the reason of the known rule of extinguishing fires by smothering them.

It is provided by statute, that wood fuel shall not be sold under the size. See BILLET and FAGGOTS.

FUGA dæmonum, in *Hermy*, a name used by some authors for the hypericum, or St. John's wort.

FUGA vocis, in the *Ancient School Philosophy*, a supposed aversion in nature to a VACUUM.

Most of the phenomena which the ancients ascribed to the *fuga vocis*, the moderns have demonstrated to arise from the gravity and pressure of the air. This is the case in the ascent of water in syringes, pumps, &c.

FUGALIA, in *Antiquity*, a feast celebrated among the Romans, supposed by some to be the same with the REGIFUGIUM, held on the 24th of February, in memory of the expulsion of the kings, and the abolishing of the monarchical government. Struvius, Antiq. Rom. Syntag. cap. 9. distinguishes the *fugalia* from the *regifuge*; and even doubts whether the *regifugium* were thus called on account of the expulsion of the kings, or because the *rex sacrorum*, after the sacrifice was ended, fled hastily out of the forum and curia.

Be this as it will, the only ancient author of note that makes express mention of the *Fugalia*, is St. Augustine De Civitate Dei, lib. ii. cap. 6. And his commentator Vives shews a great inclination to correct the reading of the word, were it not that St. Augustine adds, that the feast was a true *Fugalia*, all decency and modesty being banished from it.

That learned person conjectures, that the *Fugalia* were the same thing with the *Pepisugia*, or the feast of *Fugis*, the goddesses of joy, occasioned by the rout of an enemy, which was the reason why the people abandoned themselves to riot and debauchery; and that the feast was first instituted on occasion of the victory gained over the Etruscans, Fidenates, and neighbouring nations, upon their attempt to take possession of Rome the day after the people had withdrawn from it, as related by Varro, lib. v. de Ling. Lat.

But, according to Varro, the *Pepisugia*, which fell in the month of June, were held in memory of the flight or retreat of the people, in a sedition raised among them: it is true, he adds, that the day followed soon after the retreat of the Gauls, and the time when the neighbouring nations conspired against them: but this does not appear to have any relation to the *Pepisugia*, being only meant to mark the era or time when the sedition and flight of the Roman people happened. After all, though the *Pepisugia* might have been originally established in commemoration of the flight of the people, and not that of the enemies, this does not hinder, but the *Fugalia* of St. Augustine may probably be the *Pepisugia* of Varro, according to the conjecture of Vives.

FUGAM fecit, in *Law*, a term used where it is found by inquisition, that a person fled for felony, &c. And if flight and felony be found on an indictment for felony, or before the coroner, where a murder is committed, the offender shall forfeit all his goods, and the issues of his lands, till he is acquitted or pardoned; and it is held, that when one indicted of any capital crime, before justices of oyer, &c. is acquitted at his trial, but found to have fled, he shall, notwithstanding his acquittal, forfeit his goods, but not the issues of his lands, because by the acquittal the land is discharged, and consequently the issues. 3 Inst. 218. H. P. C. 27. 2 Hawk. P. C. 450. The party may, in all cases, except that of the coroner's inquest, traverse the finding of a *fugam fecit*; and the particulars of the goods found to be forfeited, may be always traversed; also whenever the indictment against a man is insufficient, the finding of a *fugam fecit* will not hurt him. 2 Hawk. 451. Making default in appearance on indictment, &c. whereby outlawry is awarded, is a flight in law.

FUGITIVE, *refuge*, a person obliged to fly his country, or remove from a place where he had some abode or establishment, on account of his crimes, debts, or on other occasions.

In the Roman law, a *fugitive* slave was such a one as was apt to run away from his master. And in selling a slave, the master was obliged to declare, whether or no he were *fugitive*.

The term is also applied to deserters in an army, or those who fly from the combat.

FUGITIVES goods, *bona fugitivorum*, the proper goods of him that flies upon felony, which, after the flight lawfully found on record, do belong to the king, or lord of the manor.

FUGITIVES over sea, are persons that go over sea without the king's licence, who, unless they are merchants, or eminent persons, or king's soldiers, forfeit their goods; Vol. II No 143.

and masters of ships, &c. carrying such persons beyond sea, shall forfeit their vessels; and also, if the searcher of any port shall negligently suffer any persons to pass, he shall be imprisoned, &c. Stat. 9 Edw. III. cap. 10. and 3 Ric. II. cap. 2.

FUGITIVE pieces, among the learned, denote those little compositions which are printed on loose sheets, or half sheets; thus called, because easily lost, and soon forgot.

FUGUE, of *fuga*, flight, in *Music*, is when the different parts of a musical composition follow each other, each repeating what the first had performed.

There are three kinds of fugue; the *single fugue*, *double fugue*, and *counterfugue*.

FUGUE, *single*, or *simple*, is some point consisting of 4, 5, 6, or any other number of notes, begun by one single part, and then seconded by a third, fourth, fifth, and sixth part, if the composition consists of so many, repeating the same, or such-like notes; so that the several parts follow, or come in, one after another, in the same manner, the leading parts still flying before those which follow.

FUGUE, *double*, is when two or more different points move together in a *fugue*, and are alternately interchanged by several parts.

For the *Counter FUGUE*, see COUNTER-fugue.

The Italians say, a *fugue* or *flight* of *rooms*, or *chambers*, meaning a series or range of rooms, the doors whereof answer in a right line behind each other, so as they may be all seen at once, from one extreme to the other.

FULCRUM, *Prop*, in *Mechanics*. See LEVER, and HYPOMOCHLION.

FULGURATING phosphorus, a term used by some English writers to express a sublance of the phosphorous kind, the preparation of which does not seem to have been well known to any but the inventor of it. It was prepared both in a liquid and a dry form, and not only shone in the dark in both states, but communicated its light to the things it was rubbed on. If inclosed in a glass vessel well stopp'd, it sometimes would *subscindere*, or throw out little flashes of light, and sometimes fill the whole vessel with waves of flame. It does not need recruiting its light at the fire, or in the sunshine, like the phosphorus of the Bolesian hope, but of itself continues in a state of shining for several years together, and is seen as soon as exposed in the dark; the solid or dry matter always resembling a burning coal of fire, though not consuming itself. Phil. Trans. No 134. See PHOSPHORUS.

FULICA, in *Zoology*. See COOT.

FULIGINOUS, an epithet applied to a thick smoke, or vapour, replete with soot or other crass matter.

The word is formed from the Latin *fuligo*, soot; and is rarely used but when joined with vapour.

In the first fusion of lead, there exhales a great deal of *fuliginous* vapour, which, retained and collected, makes what we call LITHARGE.

Lump-black is what is gathered from the *fuliginous* vapours of pines, and other resinous woods, when burnt. Some physicians talk of *fuliginous* vapours emitted from the spleen to the brain, which they will have to be the cause of the hypochondriac and hysterical disorders; thence called the vapours, and by some the spleen.

FULIGO metallorum, a term used by the *Chymists*, sometimes to express arsenic, and sometimes crude mercury.

FULIGULA, in *Ornithology*, a name given by Gelfer to a species of duck, seeming to be the same with a kind common on the Yorkshire shores. The same author also describes another species under the name of *anas fuligula prima*, which seems the same with the *CAPO NEGRO*, or *tufted duck*.

FULL is variously used in opposition to empty, narrow, confined, &c.

The Cartesians hold, that the universe is *full*, i. e. that every part or point has matter in it.

When the body is *full* of humours it should be purged. See PLETHORA, and PLETHORA.

An ambassador has *full* power given him to act, transact, &c. The army was in *full* march, i. e. the whole army was in march, with all the forces it consisted of.

A man is said to bear the arms of a family *full*, i. e. without any difference or diminution.

FULL eye. See AOR, in *Law*.

FULL arm. See ARM.

FULL forfeiture. See FORFEITURE.

FULL moon, *plenilunium*, that phase of the moon, when her whole disk or face is illuminated; which is in the time of her opposition to the sun.

Eclipses of the moon always happen at the time of *full* moon. See ECLIPSE.

FULL and by, a *Sea-phrase*, denoting the situation of a ship with regard to the wind, when the is close-hauled, and sailing in such a manner, as neither to steer too nigh the direction of the wind, nor to deviate to leeward, both

of which movements are unfavourable to her course; as in the former her sails will shiver, and render the effort of the wind precarious and ineffectual; and in the latter she will advance in a direction widely distant from her real course. Hence, keep her full in the order from the pilot or other officer to the helmsman, not to incline too much to windward, and thereby shake the sails so as to retard the course. Falconer.

FULLER, a workman employed in the manufactories, to full, mill, or scour cloths, rateens, ferges, and other woollen stuffs, by means of a mill, to render them thicker, and more compact and durable.

The word is formed of the Latin *fulli*, which signifies the same thing.

The *fullers* among the Romans washed, scoured, and fitted up cloths; and their office was judged of that importance, that there were formal laws prescribed them for the manner of performing it. Such was the *Lex Metallæ de Fullanibus*. See also Pliny, lib. vii. cap. 56. Ulpian. leg. 12. ff. de Fortis, lib. xiii. § 6. Locati, lib. xii. § 6. ff. &c. See **FULLING**.

FULLERS-EARTH, *fulvicola*, or *cinis purpurascens*, is a hard, dense MARLE, moderately heavy, of a very compact and regular texture, of a rough or dry appearance, though, when cut or scraped, it is of a very smooth, unctuous, and glassy surface; it does not colour the hands, adheres but slightly to the tongue, melts freely in the mouth, and has a little harshness between the teeth; in water it is immediately diffusible, and falls into a fine soft powder. It makes no effervescence with aqua fortis; in the fire it acquires a yellowish brown colour, and a stony hardness: the natural colour of the *fullers-earth* is commonly a greyish brown; but it much varies, and is found from the pale greyish brown to the dusky and almost black, generally with a cast of yellowish green. This substance is of great use in the woollen manufacture.

It serves to scour cloths, stuffs, &c. and imbibe the tar employed in the external distemperatures of sheep, and all the grease and oil, and other unctuous substances, necessarily used in the preparing, dressing, &c. of the wool. *Fullers-earth* is dug in great plenty out of certain pits near Brick-hill, in Staffordshire; also near Ryegate, in Surrey; near Middlestone, in Kent; near Natley and Petworth, in Sussex.

But the greatest quantity and the finest earth of this kind in the world, is dug in the pits at Wavendon, near Woburn, in Bedfordshire. The strata in these pits lie thus; from the surface to the depth of six yards, there are several layers or beds of sand, all reddish, but some lighter coloured than others. Under these there is a thin stratum of a sand-stone, which they break through, and then for the depth of about seven or eight yards you have sand again, and then there is the *fullers-earth*. The upper stratum of this is about a foot thick, and they call it **CLEDGE**; this is thrown aside as useless, being commonly fouled with the sand, which originally covered it, and usually infiltrates itself considerably into it. After this they come at the fine *fullers-earth* for sale, which lies to the depth of eight feet more. The matter of this is divided into several layers, there being commonly about a foot and half between one horizontal fissure and another. Of these several layers, the upper half, where the earth breaks itself, is tinged red; this seems to be owing to the running of the water on it, from among the sands above, some of which are probably of a ferruginous nature, or have ferruginous matter among them. This reddish *fullers-earth* the workmen call **CROP**; and between the cledge and this, there is a thin stratum of matter of less than an inch, which is white, colour, and external appearance, resembles the terra japonica of the shops. This may probably also have a share in the tinging of the earth, as the water may be coloured in running through it.

The lower half of the strata of *fullers-earth* they call **WALL-EARTH**; this is untinged with the red colour of the other, and seems the most proper for fulling. Under the *fullers-earth* there is a stratum of a rough and coarse white stone, about two feet thick; they seldom dig through this, but if they do, they find more strata of sand.

The stratum of *fullers-earth* forms all the way to lie very level, not to rise and fall with the upper strata, for when the surface is higher, they always find they have farther to dig for it. There are a great number of perpendicular fissures in the stratum of *fullers-earth*, and besides this, it forms itself in every interval into a multitude of pieces of different shapes and sizes by cracking. The place where it is dug, is that ridge of sand-hills which runs to Shooter, in Oxfordshire; and as the strata of the earth are usually found to continue much the same, for long tracts of ground, it is probable that the *fullers-earth* stratum runs the whole length of these hills, and that

somebody will at one time or other be enriched by finding it in some other part of their course. Phil. Trans. N° 379. or Abridg. vol. vi. part ii. p. 220, &c. It is absolutely necessary to the well dressing of cloths; and hence foreigners, though they can procure wool to be clandestinely exported out of the kingdom, can never reach to the perfection of the English cloths, &c. without *fullers-earth*, which is very plentiful in England, and exceeds that of other countries in quality, as much as in quantity and cheapness.

For this reason it is made a contraband commodity; and the export made equally criminal with that of exporting wool.

Abroad they make great use of urine, in lieu of *fullers-earth*.

This earth abounds much in the vegetative salt which promotes the growth of plants, and is therefore reckoned by Sir H. Plar, and others, a great improver of land. When mixed with vinegar, it disperses pimples and potholes, checks inflammations, and cures burns. See **CUMULATA**.

FULLERS-USED, *thistle*, or *tonne*, in *Botany*. See **TRAZEL**. **FULLERY**, a work-house, or place where cloths, &c. are full'd or scour'd.

The term is principally understood of the fulling-mill.

FULLING, the art, or act of cleansing, scouring, and pressing cloths, stuffs, and stockings, to render them stronger, closer, and firmer; called also *millling*.

Pliny, lib. vii. cap. 56. assures us, that one Nicias, the son of Hermias, was the first inventor of the art of *fulling*; and it appears by an inscription quoted by Sir G. Wheeler, in his Travels through Greece, that this same Nicias was a governor in Greece in the time of the Romans.

The *fulling* of cloths, and other stuffs, is performed by a kind of water-mill; thence called a *fulling*, or *sewing-mill*.

These mills, excepting in what relates to the mill-stones and hopper, are much the same with corn-mills. And there are even some which serve indifferently for both purposes; corn being ground, and cloths full'd, by the motion of the same wheel.

Hence in some places, particularly France, the fullers are called *millers*; as grinding corn and milling stuffs at the same time.

The principal parts of the *fulling-mill* are, the wheel with its trundle; which gives motion to the tree or spindle, whose teeth communicate it to the pestles, or flampers, which are hereby raised and depressed alternately, according as its teeth catch on, or quit, a kind of latch in the middle of each pelle. The pestles, and troughs are of wood; each trough having at least two, sometimes three pestles, at the discretion of the miller, and according to the force of the stream of water.

In these troughs are laid the cloths, stuffs, &c. intended to be full'd; then, letting the current of water fall on the wheel, the pestles are successively let fall thereon, and by their weight and velocity they stamp and press the stuffs very strongly, which by this means become thickened and condensed.

In the course of the operation, they sometimes make use of urine, sometimes of *fullers-earth*, and sometimes of soap.

To prepare the stuffs to receive the first impressions of the pestles, they are usually laid in urine; then in *fullers-earth* and water; and lastly in soap, dissolved in hot water.

Soap alone would do very well, but this is expensive; though *fullers-earth*, in the way of our dressing, is superior to it; but then it must be first well cleared of all stones and grittiness, which are apt to make holes in the stuff.

As to urine, it is certainly prejudicial, and ought to be entirely discarded; not so much on account of its ill smell, as of its sharpness and faltness; which is apt to render the stuffs dry and harsh.

The true method of *fulling* with soap is delivered by Mons. Colmet, in an authentic memoir on that subject, supported by experiments made by order of the marquis de Louvois, then superintendent of the arts and manufactures of France. The substance of which we shall here subjoin.

FULLING, cloth and woollen stuffs, with soap, method of. A coloured piece of cloth, about forty-five ells, is to be laid in the usual manner, in the trough of a *fulling-mill*, without first soaking it in water, as is commonly practised in many places.

To full this trough of cloth, fifteen pounds of soap are required; one half of which is to be dissolved in two pails of river or spring-water, made as hot as the hand can well bear it. This solution is to be poured by little and little upon the cloth, in proportion as it is laid in the trough;

trough: and thus it is to be *fulled* for at least two hours; after which it is to be taken out, and stretched.

This done, the cloth is immediately returned into the same trough, without any fresh soap; and there *fulled* two hours more. Then taking it out, they wring it well, to express all the grease and silt.

After the second *fuling*, the remainder of the soap is melted, as the former, and cast out four different times, on the cloth; remembering to take out the cloth every two hours, to stretch it, and undo the plaits and wrinkles which it has acquired in the trough. When they perceive it sufficiently *fulled*, and brought to the quality and thickness required, they scour it out for the last time in hot water, keeping it in the trough till it be quite clean. As to white cloths, because these *full* more easily, and in less time, than coloured ones, a third part of the soap may be spared.

FULLING of stockings, caps, &c. may be performed somewhat differently; viz. either with the feet, or the hands; on a kind of rack, or wooden machine, either armed with teeth of the same matter, or else with hories or bullocks teeth. The ingredients made use of herein, are urine, green soap, white soap, and fullers-earth. But water softened with chalk is far preferable.

Note, woven stockings, &c. should be *fulled* with soap alone; for those that are knit, fullers-earth may be used with the soap.

Indeed, it is frequent to *full* these kinds of works with the mill, after the usual manner, of cloths, &c. But that is too coarse and violent a manner, and is apt to damage the work, unless it be very strong.

FULLO, in *Ichthyology*, a name given by Theodore Gaza, and others to the *TENCH*, or black *oprinus*, called by the Greeks *phjra*.

FULLONIANI, in *Church History*, heretics who anathematized all who did not acknowledge, that Christ suffered in his divine nature; or who distinguished his human and passible nature from his divine and impassible. See *TRITHEMIUS*.

FULLONICA terra alba, white fullers' earth, in *Natural History*, a name given by some authors to the common white tobacco-pipe clay. See *CIMOLIA alba*.

FULLONUM carduus. See *TEAZEL*.

FULMAR, in *Ornithology*, a species of *præciliaria* or *petrel*, that inhabits the life of St. Kilda; appearing there in November and continuing through the whole year, except the months of September and October. It lays a large white and brittle egg, which is hatched in June. This bird is superior in size to the common gull; the bill is strong, hooked at the end, and of a yellow colour. The nostrils are composed of two large tubes, lodged in one sheath; the head, neck, inferior part of the body, and tail are white; the back and coverts of the wings ash-coloured; the quill-feathers dusky, and the legs yellowish. Instead of a back-toe, it has only a sort of spur, or sharp straight nail. The food of these birds is the blubber or fat of whales, of which they are very voracious; inasmuch that the whales are discovered at sea by the flights of these birds; this is soon converted into oil and spotted from their bills in large quantities for their defence and for the supply of their young. This oil, it is said, has been successfully used in rheumatic cases. The *fulmar* is of singular use to the islanders, as it supplies them with oil for their lamps, down for their beds, a delicacy for their tables, a balm for their wounds, and a medicine for their distempers. The *fulmar* is also a certain prognosticator of the change of the wind; because, if it comes to land, no well wind is expected for some time; and the contrary, when it returns and keeps at sea. Pennant.

FULMINANT, **FULMINANS**, or **FULMINATING**, an epithet applied to something that thunders, or makes a noise like that of thunder.

We say, *Jupiter fulminans*, *aurum fulminans*, *pulsis fulminans*, &c. The *Jupiter fulminans* and the *Jupiter fulgurans* seem to have been very much of the same kind; but if they are distinguished, we may consider the former as the dispenser of the lightnings which are darted from the clouds, and the latter as the dispenser of those lesser lightnings that only shoot about and struggle amidst the clouds.

FULMINANS, Aurum. See **AURUM**.

FULMINANS, Pulsis, is a composition of three parts of nitre, two parts of salt of tartar, and one of sulphur. Both the *aurum* and *pulsis fulminans* produce their effect principally downwards: in which they differ from gunpowder, which acts in *arbor*; but principally upwards. If they be laid in brass ladles, and so set on fire; after fulmination, the ladles will be found often perforated. Moreover, this powder does not require to be forcibly confined, as gunpowder does, in order to make a great explosion, and the heat must be applied to it slowly. We may also observe that some instants before its explosion, a

light blue flame appears on its surface, which is nothing else than the phlogistic vapours beginning to kindle. No more fire or flame is perceived, during its fulmination; the explosion being so quick and the commotion so violent, that the flame is suffocated and extinguished as soon as it is formed and before it can be perceived. Nor does the *fulminating powder* generally kindle the combustible bodies in contact with it, because the time of its inflammation is too short.

FULMINATING damp. See **DAMP**.

FULMINATING Legion. See **THUNDERING Legion**.

FULMINATION, in the *Romish Canon Law*, a sentence of a bishop, official, or other ecclesiastic appointed by the pope; whereby it is decreed, that some bull, dispensation, or rescript, sent from the pope, shall be executed.

Fulmination is the same thing with the verification, or recognition, of a letter, or instrument, of a prince in a lay court.

FULMINATION is also used for the denunciation, or execution, of a sentence of ANATHEMA, made in public, with due solemnity.

In *fulminating anathemas*, the bishop who pronounces sentence, is to be clothed in his episcopalia, and accompanied with two priests in surplices; after sentence is pronounced, they cast down to the ground the lighted wax-tapers which they held in their hands.

FULMINATING, or **FULGURATING**, in *Chemistry*, a vehement noise, or shock resembling thunder, occasioned by the sudden explosion and inflammation of divers preparations; as *aurum fulminans*, &c. when set on fire.

FULUSCULUM, in *Botany*, a name given by the ancient Romans to a peculiar species of mullein or *verbascum*, of which they used to make the wicks of the torches with which they kindled their funeral piles. The Greeks for the same reason called this species *serenia*. Dioscorides indeed calls it *lychnitis*, *hagevris*, and Nicander, *thysyllis*, *Sponda*. The way they used to use this: they beat out the stalk of the plant, as we do hemp, and when it was separated into loose fibres, they plucked it into melted resin; this gave it a confluence again, and when cold, it was a kind of flambeau.

FUMADOES, in *Commerce*, a name given to pitchsticks, garbaged and salted, then hung in the smoke and pressed; so called in Spain and Italy, whither they are exported in great abundance. Vide Stat. 14 Car. 2. cap. 21.

FUMAGE, a term used in some parts of the kingdom, for dung, or manuring with dung.

FUMAGE. See **FUAGE**.

FUMARIA, see **FUMITORY**.

FUMER, in *Zoology*, see **POLE-CAT**.

FUMET, a term used among sportsmen for the ordure or dung of harts; otherwise called *sewmet*.

FUMIGATION, in *Medicine* and *Chemistry*, is understood of things taken in the way of fume, or smoke; or that are turned into smoke or steam.

The *fumigations* prescribed by dispensatory writers are reduced to two kinds; the one conducive to health, the other only to pleasure; and of each kind some are of moist, or liquid ingredients, others of dry ones.

The *fumigations* for pleasure are composed of fragrant and sweet-scented substances, and are used in form of powders, troches, or medicated candles. The first are usually prepared of storax, benjamin, lignum aloë, cinnamon, camphor, musk, ambergris, and civet, mixed in due quantities, and all reduced together to a powder. The second kind, or troches, are composed of the same kind of powdered ingredients, and are made into a paste with a mucilage of gum tragacanth, and then cut into form.

And the last kind, or candle *fumigations*, are prepared of the melted sweet gums, with benjamin, made up into the form of large candles, with as much of the before mentioned sweet ingredients as can be received into the mass. These, though only meant for luxury and pleasure, yet have medicinal virtues; and as they abound in cordial substances, cannot but revive the spirits, and resist contagion. The moist *fumigations* of this kind consist of the powders before named, blended among a large quantity of rose and orange-flower water, and of solutions of storax, and other of the sweet gums in spirit of wine.

The *fumigations* used to restore health are of several kinds. Some are meant only as corroboratives, and these are composed of much the same ingredients with those used for pleasure; others are used to dry up abundant humours, to purge the lungs, or to promote the menses. In all disorders of the uterus, there should be added to these *fumigations*, galbanum, castor, and ass's foetida. A common *fumigation* is also used, by throwing tobacco on coals, and receiving the smoke through a funnel; and to this are sometimes added colt's foot leaves, with other peccoral herbs, and a little sulphur. These are very useful for drying up ulcerations of the lungs, and other disorders of the breast.

The moist *fumigations*, for the sake of health, consist either of some simple liquor, such as vinegar, wine, aqua vite, or rose-water; and in some cases, as for the dissolving hard tumors, a red hot brick, or stone, is thrown into vinegar, and the steam is received on the part. This is also a *fumigation* often used in times of pestilential contagion, and that with great success. Decoctions of uterine herbs are also frequently used for *fumigations* in several disorders of the womb.

Olibanum, amber, storax, and balsam of Tolu, make a fine dry *fumigation* for a catarrh; and in hysterical cases, great benefit is often found from holding the head, with the mouth open, over a hot solution of an ounce of assafoetida in a pint of strong wine-vinegar.

A northern physician has an express treatise to justify the use of *fumigations* in many cases.

It is dangerous taking mercury by *fumigation*. This *fumigation* is a kind of potential calcination; the vapour of mercury, laid on the fire, corroding and reducing into a calx the little laminae of metals suspended over it.

Fumigations with cinabar have often been recommended as very efficacious in some of the worst circumstances of the venereal disease. From a case related in the *Medic. Edinb.* vol. iv. art. 8. it appears, that this practice may be attended with very violent effects. Half a dram of factitious cinabar burnt under the nose and mouth of the patient, is there mentioned as having raised a spitting in three hours.

FUMIGATION, *præter se*, was invented at Moscow, in 1771, for preventing the infection of the plague. It is prepared of different degrees of strength in the following manner: 1. Take leaves of juniper, juniper-berries pounded, ears of wheat, guaiacum wood pounded, or, if this cannot be had, the cones of pines or firs, of each six pounds; common salt-petre pounded, eight pounds; sulphur pounded, six pounds; Smyrna tar or myrrh, or, instead of this, the common tar of pines and firs, two pounds; mix all these ingredients together, and they will produce a pound of the powder of the first strength. 2. Take fourteenth-ore or mugwort, cut into small pieces, five pounds; leaves of juniper, cut in the same manner, four pounds; juniper-berries pounded, three pounds; common salt-petre pounded, four pounds; sulphur pounded, two pounds and a half; Smyrna tar or myrrh, one pound and a half; mix these together, and they will yield half a pound of the powder of the second strength. The efficacy of the powder of *fumigation* was tried on ten malefactors under sentence of death, who were confined three weeks in a lazaretto, and exposed in every possible way to the infection of the plague, and none of them were at all injured by it.

FUMIGATION is also used for the act of making a suspended body receive the fumes or beams of one or more other bodies, in order to calcine it, to correct it, or impart to it some new quality.

Cerufs is made by the *fumigation*, or vapour, of vinegar, gnawing and corroding plates of lead.

FUMIGATOR, formed of *fumus*, fume, in Surgery, an instrument used for injecting cylinders of the smoke of tobacco. Cylinders of this kind have been applied in the *iliac fossæ*, in the *hernia intercostalis*, and in other cases of an obdurate constipation, or obstruction of the bowels; and as they are admirably adapted to excite the suspended or extremely languid peristaltic motion of the intestines, which are reckoned among the most irritable parts of the body, and are allowed to retain the vital influence longer than any other, they have been peculiarly serviceable in cases of recovery from apparent death by *drowning*, &c. The instrument commonly used for the injection of these cylinders is formed with an iron or brass capsule for containing a certain quantity of tobacco, to which capsule are fastened two pipes; one of them made of bone, to be inserted into the anus; and the other of ivory, in the shape of that end of the trumpet which is applied to the mouth; by means of which the smoke of the burning tobacco in the capsule is forced through the first pipe into the anus. The Dutch have made the bowl of this instrument large enough to contain three fourths of an ounce of tobacco; it is constructed of wood, lined with brass or tin, and covered by a top of wood lined in the same manner; the top is screwed upon the tube; the instrument is used by means of a wooden tube or blow-pipe, screwed to the top, and adapted either to the mouth, or to a pair of bellows. The instrument used by the French is composed of a box resembling the bowl of a pipe, covered by a lid, at the upper part of which is a hole or chimney, for giving air to the tobacco at pleasure. From the side of this cover proceeds a tube, about four inches in length, incorporated with it, and adapted at the other extremity to the end of a flexible tube. At the lower part of this box is inserted a kind of tubular handle, which admits the nozzle of a pair of

bellows, fastened to it by means of an iron pin passing transversely through both. By this contrivance, when the tobacco is lighted, it is not necessary to touch the heated box; and the bellows serves as a handle by which to direct all the necessary movements: the whole instrument is made of copper.

Mr. Wrigglesworth, in consequence of hints and observations communicated to him by Dr. Cogan, has constructed a *fumigator* free from the inconveniences attending those already mentioned. The bowl or body of this new instrument is made of cast brass, and is large enough to contain about an ounce and a half of tobacco. The pipe projecting from the lower part of it is bored out of a solid piece of brass, and also those to which each extremity of the leathern tube is affixed. The cover is likewise made of cast brass; from the upper extremity of which projects a neck about an inch and a half in length, the opening or bore of it being about half an inch in diameter. The cover is fixed to the box by means of two niches made on each side of a circular ridge or edge, admitting two ears, that project from the upper part of the box, which by a circular motion lock upon the brim. The nozzle of the bellows is accurately adapted to the neck of the cover, and is about an inch and a half or two inches long; the lower end of the nozzle is rounded and smooth, like the lower extremity of a glyster-pipe, and perforated like a cannula, in order to prevent the ashes of the tobacco from rising into the bellows. The bellows are fastened upon the cover or lid in a manner similar to the preceding; an ear projects from the upper part of the neck, and is admitted into a notch, in a circular rim, upon the nozzle. The pipe projecting from the lower extremity of the bowl, locks into the cross-pipe to which the leathern tube is affixed, in the manner of a bayonet. By this kind of fastening the whole apparatus may be made ready in the space of a minute, and forms one compact body, free from the hazard of falling in pieces, and thus interrupting the operation; and yet either part may be taken off when the occasion requires, with the utmost ease and expedition. The bowl is inclosed in a thick case of wood, removable at pleasure, which secures the hand from injury during the whole process. The same ingenious artist has also constructed a machine so formed, as to contain the above described *fumigator*, with every requisite for beginning an operation in the recovery of persons apparently drowned, &c. such as brandy, salt, spirit of sal ammoniac, tinder-box, flint and steel, and cloths to rub the body. This machine is light and portable, being not much larger than a case of surgical instruments. Reports of the Humane Society, 1775. p. 82, &c.

FUMING, in *Metallurgy*, the first calcination of the ores of metals, intended to divert them of their sulphurs. See **ROASTING**.

FUMITORY, *Famaria*, in *Botany*, a genus of the *diadelphe hexandra* class; the embleme of the flower is composed of two equal opposite leaves; the flower is of the tingent kind, approaching nearly to the butterfly flowers; the upper lip is plain, obuse, and reflexed; the nectarium at the base is obtuse and little prominent; the under lip is like the upper; but the base is keel-shaped; the chaps of the flower are four-cornered, and perpendicularly bifid; there are two equal broad lamina in each flower, included in the two lips, each being terminated by three summits. In the centre is situated an oblong germen, which afterwards becomes a short pod with one cell, including roundish seeds. There are twelve species. Miller.

The common *fumitory*, which is frequent in our gardens and corn-fields, and flowers from April to June, is esteemed a very great medicine in obstructions of the liver and spleen; it attenuates crass, viscous, and adust humours, and carries them gently off by stool and urine. It is famous for the scurvy, and is also given in *insaniam* in the jaundice, and in the itch, and all other cutaneous disorders.

FUNAMBULUS, among the Romans, was what we call a rope-dancer, and the Greeks, *skambotata*. The term is also used for such as, letting themselves down by a rope, or cord, make their escape out of a city, or place besieged, as is observed by Du-Cange.

Julius Capitolinus, and Horace, make mention of *funambuli*. Acron on Horace assures us, that it was the orator Metellus who first introduced the word *funambulium*, in lieu of *skambotata*, used by the Greeks. For the Greeks seem to have had some of these rope-dancers from the first institution of their scenic games, which are said to have been invented about the time of Ixionius, father of Erigone; or of Dionysius, surnamed Liber Pater, whom Theophrastus first introduced into Athens.

At Rome, the *funambuli* first appeared under the consulate of Sulpicius Peticus and Licinius Stolo, who were

the first introducers of the scenic representations. It is added, that they were first exhibited in the island of the Tiber; and that the consors Messala and Callius afterwards promoted them to the theatre.

In the *Flautia*, or *ludi Flautales*, held under Galba, there were funambulatory elephants, as we are informed by Suetonius. Nero also shewed the like, in honour of his mother Agrippina. Vespasian relates the fame of the time of Carinus and Numerianus.

There was a *f-ambulus*, it seems, who performed at the time when the *Hevora* of Terence was acted; and the poet complains, that the spectacle prevented the people from attending to his comedy; *Ita populus stultus stupidus in funambulo antonem accipit*.

FUNCTION, the act of doing something for which the agent was appointed, or which he was obliged to.

Thus we say, the stomach performs its function, i.e. digests well; the fumes of wine disturb the brain in the performance of its functions.

Physicians divide the functions of the human body into vital, natural, and animal.

FUNCTIONS, vital, are those necessary to life; and without which it cannot subsist: as, the actions of the heart, brain, lungs, &c.

FUNCTIONS, natural, are those which change the food, &c. so as to assimilate it to our own nature: such are the actions of the viscera, and the vessels which receive, retain, secrete, &c. the humours.

FUNCTIONS, animal, are those without which we cannot perceive, will, remember, &c. Such are feeling, seeing, imagining, judging, passions, voluntary motions, &c.

FUNCTION is also used figuratively in speaking of the office, duties, or occupations a person is engaged in.

The actions of an ambassador must be distinguished from his functions; the one regard his character, the other his person.

FUNCTIO. The term function is used in algebra; for an analytical expression any way compounded of a variable quantity, and of number, or constant quantities: therefore every analytical expression, in which, besides a variable quantity x , there are constant quantities, is a function of x . Thus $a + 3x$, $x - 4xy$, $a + b\sqrt{a-x}$, c^2 , &c. are functions of x .

The difference of functions consists in the manner in which they are compounded; and depends, therefore, upon the operations by which quantities may be compounded and mixed. These operations are, addition, subtraction, multiplication, and division, the raising to powers, and extraction of roots, to which the resolution of equations ought to be referred. Beside these operations, which are called algebraical, there are other transcendental ones; such as exponential, logarithmic, and many others, arising from the inverse method of fluxions. Functions may arise from the most simple and analytical operations: thus we have the multiple functions $2x$, $3x$, $\frac{1}{2}x$, $2x^2$, &c. and the powers of 2 , as 2^x , 2^x , 2^{-x} , &c. are called functions.

Functions are divided into algebraical and transcendental: algebraical functions are those formed by algebraic operations only; such are those above specified, except c^2 , which belongs to the following species.

Transcendental functions are those formed by transcendental operations: such are exponential quantities or powers, the exponents of which are variable quantities; whereas, in algebraic functions the exponents are always constant quantities.

It is to be observed as to transcendental functions, that those functions only of a variable quantity are to be deemed transcendental, which not only enter the composition with, but also effect the variable quantity: thus if x signifies a circular arc, or a logarithm, then will c^x , and the like expressions, be transcendental functions of x . But if the transcendental operation operates only on constant quantities, the function is no more than algebraic: thus if c denote the circumference of a circle, the radius of which is $=1$, c will be a transcendental quantity, and yet the expressions $(+c)$, $(-c)$, $4c^2$ are but algebraic functions of x . Some indeed have doubted whether c ought to be ranked among algebraic functions, or not; but the doubt is of small weight. And some choose to call the powers of x , the exponents of which are irrational numbers, *intermediate functions*: thus, $x^{\sqrt{2}}$ is an intermediate function of x .

On the subject of functions, their divisions, transformations, explication by infinite series, &c. Mr. Euler should be consulted, who has treated this matter very fully in the first chapter of his *Analysis Infinitorum*.

FUND, **FUNDUS**, a Latin term, used for the bottom of certain things; and particularly of certain parts of the body.

FUND of the eye, **FUNDUS oculi**, is that part possessed by the choroides and retina.

VOL. II. N° 143.

The images of objects are represented in an inverted situation, in the fund of the eye. See **VISION**.

FUNDUS uteri, or *bottom of the womb*, is the body or principal part thereof; so called in contradistinction to the cervix, or neck; the osculum, or mouth; and the vagina, or sheath. See *Tab. Anat. (Splanchn.) fig. 9. lit. a. fig. 11. lit. d.*

FUNDUS vesicæ, or *bottom of the bladder*, is the cavity thereof, wherein the urine is contained. In men it is placed over the rectum; and in women over the matrix.

FUND of the gall bladder, the *stomach*, &c. See **GALL-BLADDER**, **STOMACH**, &c.

FUNDUS plantæ is that part of a plant, where the stalk just meets and joins the root.

FUNDUS cæci is the point opposite to the point of culmination; or the point of the ecliptic, wherein it is intersected by the meridian beneath the horizon.

FUND, in *Commerce*, is used for the capital or stock of a merchant, company, or corporation; or the sum of money that they put into trade.

In this sense we say absolutely, the funds, the public funds, meaning the stock of the great companies, or corporations, as the Bank, South Sea, East-India, &c.

FUNDUS publicæ, are the taxes appropriated by parliament to the support of civil government, and the payment of the principal and interest of money borrowed for public services. These funds in Britain, have been all formed into the four following classes or divisions; the **AGGREGATE fund**, the **SOUTH SEA fund**, the **GENERAL fund**, and the **SINKING fund**. Of all these, but more especially the last, we shall give an account in the order in which they have been now named.

The **aggregate fund** was established by an act of Geo. I. cap. 12. in 1715. It had this name given it, because it consisted of a great variety of taxes and supplies of taxes and duties which were in that year consolidated, and given as a security for the discharge of the interest and principal of debts due to the Bank of England, and some other public debts; and also for the payment of 120,000*l.* per ann. to the civil list. Into this fund are brought the two thirds and one half twelfth of tonnage and poundage; half the inland duties on tea and coffee; the house money granted by the 7th of Will. III. the duty on hops; the duties on low wines, brandy, and British spirits; all arrears of land taxes; all public monies not appropriated; the surpluses of the nine penny excise, of the five shillings of the Bank nine penny excise, of the revenues in the annuity acts of the 4th, 5th, and 6th of queen Anne, &c. and by an act of the 1st. of Geo. II. all the duties constituting the revenue of the civil list. The whole produce or income of this fund had been for a few years before 1778 about 2,600,000*l.* per ann.

The **South-sea fund** was established, by stat. 3 Geo. I. cap. 9 in 1716; and is so called, because appropriated to pay the interest of the South-sea company's capital. It consists of a duty on candles, and certain imposts on wines, vinegar, tobacco, and East India goods. Its produce of late has been about half a million per ann.

The **general fund** was also established, by stat. 3 Geo. I. cap. 7. in 1716, and consists of a justly on goods exported: a tax on hackney-coaches and chaises; duties on soap, hides, stamps, and policies of insurance; 7*ool.* per week letter-money; a moiety of the inland duties on tea and coffee; and 39,85*l.* per annum out of the hereditary excise on beer for bankers annuities. All these taxes and payments have for some years amounted to a little more than a million per ann. and are appropriated to the discharge of the interest of 7,808,087*l.* (originally 10,000,000*l.*) capital stock of South-sea annuities, together with charges of management.

All that remained of the produce of the taxes thus digested into these three funds, after satisfying the charges upon them, was in the same year 1716, carried into a fourth fund, to which was given the name of the **sinking fund**, because appropriated to the purpose of sinking the public debts. The words of the act of the 1st. of Geo. I. which established this fund, are, "All the monies to arise from time to time, as well of the excise and surplus of an act made this session for redeeming the funds of the Bank of England; and of the excise or surplus by virtue of one other act made likewise this session for redeeming the fund of the South-sea company; as also, of the excise or surplus of the duties and revenues by this act appropriated as aforesaid; and the overplus monies of the said general fund by this act established; shall be appropriated to the discharging the principal and interest of such national debts as were incurred before the 25th of December, 1716, and are declared to be national debts; and to or for no other use, intent, or purpose whatsoever." The operations and progress of this sinking fund form part

important a part of the history of Britain, that a more particular account of it will be here proper.

Before its establishment there had existed many smaller funds of the same nature; that is, such duties or taxes had been provided for paying the interests of particular loans, as afforded surpluses by which the principal itself was to be gradually redeemed: this was the common practice in the reigns of king William and queen Anne.

Molt of the public duties were given for terms of years; and at the end of those terms they ceased of course, unless continued for farther terms by new acts of parliament: and, in general, it was provided, when any money was raised, that the principal should be cancelled either by time, as in the case of the sale of long and short annuities, or by the surpluses of the duties charged with the payment of the interest. This was an excellent plan, but it was by no means carried steadily into execution. In the year 1720, molt of the long and short annuities were converted into redeemable perpetuities, at the expense of above three millions; and the surpluses of the duties charged with particular loans were often broken into, by being either charged with new loans before they had cancelled the old, or spent on current services, as to be rendered incapable of answering the end intended by them. In consequence partly of this bad management, the public debts at the accession of the house of Hanover were so much increased as to be generally reckoned insupportable; and their reduction was made one of the first objects of parliamentary attention. This gave rise, in 1716, to the institution of the *sinking fund* of which we are giving an account, the father of which was (as has been generally said) Sir Robert Walpole, but, in reality, the Earl of Stanhope. All the taxes, except the land-tax, and five pence per bushel malt-tax, were now made perpetual, and distributed into the three funds which have been described, the surpluses of which, for ever afterwards, were to be held sacred, and to be applied invariably, according to the words of the act just recited, to the redemption of the national debt. These taxes have been always voted by parliament from year to year: they are, on this account, distinguished by the name of the annual taxes, and wholly employed, as far as they will go, in bearing the current expenses of every year.

A considerate person might have suspected, that the same causes which had rendered former partial appropriations ineffectual, would derelict the efficacy of this. There formed, however, to be reason for hoping the contrary: for,

First, the future happiness and glory of the kingdom were thought to depend on this appropriation; and the law which established it was declared to be a fundamental law of the realm. In conformity to this, secondly, the words of this law were made as strong as they could well be, and, in order to give additional force to it, a repetition of it, in the same words, was inserted in an act of the 6th of Geo. I. cap. 3. Particular notice should be taken of these words: they order that all the surpluses of the taxes then made perpetual, shall be applied to the discharge of the public debts, and to no other use or intent whatever. When, therefore, a debt had been paid off, the addition arising from that payment to the surpluses (or the annuity disengaged by it) became a part of the fund, and, together with it, was to be employed in discharging farther debts. And the same being true of every successive annuity disengaged by every payment, the fund, if never misapplied, must necessarily have operated in sinking the public debt, in the same manner that money accumulates, when put out to bear compound interest. And in this way this fund did in fact operate for a few years. While in its infancy, it was watched over with great care: the improvement, and the inviolable application of it, were recommended in molt of the speeches from the throne, and echoed back in the addresses of the house of commons. It is particularly observable, that so well did our ministers then understand the nature and importance of this fund, that rather than encroach upon it, they frequently borrowed money in order to *dispay* the necessary expenses of government. From some publications in 1716 it appears, that some persons had been led to apprehend this zeal of the ministry would not be permanent, because it was not their interest to pay off the public debt, on account of the dependence and influence created by it. In answering this objection, the writers on the side of the court called such an apprehension an indecent jealousy, and took upon them to assure the public, "that in no possible exigence of affairs could our ministers ever approve of or recommend the alienation of the *sinking fund*." Happy would it have been for Britain had this proved true: but in a little time it appeared, that the apprehensions which had been styled indecent jealousies, were too well grounded. Men in power came

soon to see, that this fund was advancing too fast in its operations, and to change their zeal for it into a resolution to derelict it: this will abundantly appear from the following facts.

Charging the income of the *sinking fund* with the payment of the interest of new loans, is an encroachment upon it, no less subversive of its efficacy, than depriving it of gross sums; there being no difference between taking from it the annual interest of a loan, and that sum itself. Between the years 1727 and 1732 several encroachments of this kind had been made upon it; but, being of a less obvious nature, they passed without meeting with any particular opposition. The finishing blow was given it in the year 1733. In that year, in order to keep the land-tax at one shilling in the pound, as it had been the year before, it was necessary either to borrow half a million for the current service, or to take this sum from the *sinking fund*. The last method was chosen, and proposed by Sir Robert Walpole to the house of commons. Long and warm debates ensued. A proposal to alienate, in a time of profound peace, a fund which the law had made sacred, and the alienation of which no possible exigence of public affairs could justify, only for the sake of keeping the land-tax for one year at one shilling in the pound, justly kindled the indignation of the patriotic party. They urged the prohibition of the law, the faith of parliament, and the security of the kingdom. The proposer of the alienation was reminded of his inconsistency and treachery, in endeavouring to beat down that very monument of glory which he had boasted of having erected for himself; and Sir John Bernard warned him, that he was drawing upon himself the curses of posterity. But all arguments were vain. The ministry pleaded that the landed interest wanted ease; that there was no occasion for being in a hurry to pay the national debt; and that the circumstances of the kingdom had altered so much since the establishment of the *sinking fund*, that the competition then among the public creditors was, not who should be first, but who should be last paid. Thus argued, among others, Sir Robert Walpole. His reasons prevailed; and the house of commons, not used to refuse him any thing, consented.

The practice of alienating the *sinking fund* having been thus begun, went on of course. In the next year, or 1734, 1,200,000*l.* was taken from it. In 1735, and 1736, it was anticipated and mortgaged.

Thus expired, after an existence of a few years, the *sinking fund*; that sacred blessing (as it was once thought) and the nation's only hope. Could it have elapsed, it would long before this time have eased Britain of all its debts, and left it a safe and happy country.

In order to obtain a better sense of this, let us here compare what it would have done had it never been misapplied, with what it has done.

Though the act that established it was passed, as already said, in 1716, it did not begin its operations till 1719, when three quarters of a million in old exchequer bills were paid off with it. The intermediate time had been employed in laying the foundations of this fund, and providing an income for it, by a general reduction of the public debts, from an interest of six per cent. and other higher interests, to five per cent. What made this reduction then practicable was a rapid fall of the interest of money, which began (in consequence of an increase of trade producing an influx of money) a little before the accession. The legal interest of money was reduced in 1714, from six to five per cent. and the means used by government for accomplishing this reduction were, first, the addition (at Michaelmas 1717) of the interest of some debts bearing five per cent. to the principal, in order to make use of the produce of the taxes which should have paid the interest, in discharging the bankers' debt and some other debts bearing six per cent.

Secondly, loans of five per cent. obtained chiefly from the Bank, and the South-sea company, to pay off such of the public creditors as did not chuse to accept a lower interest than six per cent.

After this reduction, the three funds, before described, produced a surplus of above half a million per annum. In 1727 this surplus was increased to 930,103*l.* and in 1733 (the year when the practice of alienating it began) it had been increased so much by the redemptions made with it, and by a second reduction of interest, in 1727 from five to four per cent. that its medium for five years had been 1,212,000*l.* per annum. Had it, from the year 1732, been allowed to increase beyond this (except from the interest of debts paid by it), and been applied for the first twenty-five years to the payment of debts bearing four per cent. interest, and afterwards to the payment of debts bearing three per cent. it would in the present year (1779) have completed the redemption of one hundred

hundred and forty-nine millions of debt, leaving the public, during this whole period, in possession of all the surpluses which have arisen in the revenue beyond 1,212,000*l.* except those produced by redemptions. It is not possible to conceive the beneficial effects with which this would have been attended, or the vigour which would have been all along given to public credit by such a fund, and by the prospect it would have given of the total annihilation in this year of almost all the public debts, and the disengagement of taxes bringing in above five millions per ann. to be either abolished, or (should a war prove necessary) to be continued a few years longer, for carrying it on without making any addition to the public burdens. No person who duly attends to this, and wishes well to England, can avoid execrating the policy which first produced, and has since continued, the alienation of the *sinking fund*, and converted an expedient for saving the kingdom, into a supply for extravagance and a support of corruption and despotism. This, however, is a policy which it may be expected men in power will always use when they can; for few of them have ever shewn themselves superior to the temptations of power, or virtuous enough to avoid using all means to strengthen and extend it.

Many schemes of different kinds have been formed for paying the public debts; and certain it is, that nothing can be of more importance. But the nature of things doth not admit of any method of doing this so expeditiously and effectually as an unalienable *sinking fund*; for in such a fund (it has been shewn) money is improved at compound interest, and therefore in the most perfect manner. The writers, therefore, who have employed themselves in contriving such schemes might have spared their labour. The best of all schemes has been long known and established, and received all the weight and efficiency which could be given it by the most solemn acts of legislation. But no legislature can give security against itself. No parliament can do any thing which it may not undo, especially if under any undue influence.

We have now seen what the *sinking fund* would have done, had it suited the views of the British ministry in 1733 to suffer it to go on with its operations. Let us next compare this with what it has done.

In 1737 and 1738, a million of the stock of Bank annuities and two millions of the stock of South-sea annuities were redeemed with it. For twelve years after 1738, it was wholly applied to the current expenses of every year. In 1749, the interest of near fifty-eight millions of the public debts was reduced from four to three one half per cent. interest for seven years, and afterwards to three per cent. for ever; and by this third reduction, an addition was made to the *sinking fund* of near 600,000*l.* per ann. But notwithstanding this addition, no more than three millions of the public debts were redeemed by it, during the interval of peace between the years 1748 and 1756.

By an act of the 25th of Geo. II. 1752, a change was made in the *sinking fund*, which it is necessary to mention.

Before this act the *sinking fund* consisted only of the clear surpluses of the aggregate, the general, and the South-sea company's funds. By the war, which began in 1740, there was an addition made to the public debts of near thirty-two millions. This occasioned a great increase of taxes; and the practice was, whenever any new tax produced less than the interest with which it was charged, to make good the deficiency out of the *sinking fund*, and afterwards to replace the sum taken from it out of the supplies for the following year. But whenever a tax produced more than the charge upon it, the surplus, instead of being carried to the *sinking fund*, was made a part of the supplies for the year. By the act just mentioned, all the new taxes, together with all the annuities to the payment of which they had been appropriated, were ordered to be carried into the *sinking fund*, and formed into one general account. Most of the new taxes having proved deficient, this fund at first lost more than it gained by the change. But the loss was afterwards more than made up; first, by the saving which was produced by the reduction of interest from three one half per cent. to three per cent. in 1757; and, secondly, by the addition, in the same year, of the late duties to this fund, after they had completed the redemption of a million with which they had been charged in 1745.

The war which began in 1756, added seventy-one millions and a half to the public debts. This produced a new increase of taxes, which (in conformity to the consolidating act just mentioned) have been brought to the general *sinking fund* account, together with the annuities or interests with the payment of which they are charged. And it is now the constant practice, whenever a new fund or tax is created for paying the interest of a loan,

to carry both into the *sinking fund*; in consequence of which this fund gains when the tax happens to produce more, but loses when it produces less than the interest which it has been given to pay. The *sinking fund*, therefore, which, before the consolidating act, consisted only of the surpluses of the aggregate, general, and South-sea company's funds, consists now of the clear surplus of all the appropriated taxes. There is but one tax excepted; and that is, the additional tax upon houses and windows, granted in 1758 towards paying the interest of four millions and a half then borrowed. This tax has never been made a part of the *sinking fund*; and, having always proved deficient to the amount of about 45,000*l.* per ann. the deficiency is constantly made good by the *sinking fund*, and afterwards replaced from the supplies.

Before the last reduction of the interest of the public debts, the *sinking fund*, having suffered greatly from various encroachments upon it, produced little more than a million per ann. But after this reduction, and its increase by the addition of the late duties, it produced near two millions per ann. In 1764 it produced at Michaelmas, after making good deficiencies, 2,105,000*l.* nearly. For five years after 1764, its average produce, reckoned to Christmas in every year, was 2,237,780*l.* For five years, ended in 1774, its average produce was 2,610,794*l.* In 1775, it produced 2,917,869*l.* In 1776, 3,166,517*l.* In 1777 it was charged with an annuity of 100,000*l.* per ann. to the civil list, and, after paying this annuity and half a year's interest of five millions borrowed in that year, it produced nearly 2,700,000*l.* In 1778 it was taken at three millions; but did not produce, after paying the said annuity, and making good the interests of the new loans in 1777 and 1778, more than two.

It appears from this detail, that since the peace in 1763 the income of the *sinking fund* has increased considerably. The causes of this have been partly the falling in of life annuities, and the greater productiveness of the taxes occasioned by the increase of luxury. But the principal cause has been the falling in of the interest of about ten millions and a half of the public debts, which had been discharged during the twelve years of peace between 1763 and 1775. This diminution of the public debts has been made, not by the *sinking fund*, but by a contribution from the East-India company of 400,000*l.* per ann. begun in 1768, and continued for five years; by the profits of ten lotteries; by the composition for maintaining French prisoners; sale of French prizes taken before the declaration of war in 1756; and other extraordinary receipts, amounting in all to above eight millions. This fund, therefore, did not pay off more than two millions and a half, the rest of its produce having been employed in bearing the expenses of the peace establishment, which, during this period, was nearly double to what it had been in any former period.

To the sum just mentioned, add three millions paid off in the peace between 1748 and 1756, and three millions paid off in 1736 and 1737, and it will appear that the whole amount of the public debts paid off by the *sinking fund*, since its first alienation in 1733, is only eight millions and a half; whereas it has been shewn, that had only 1,212,000*l.* per ann. of it been applied invariably to the redemption of the public debts, one hundred and forty-nine millions would have been paid, and consequently the nation extricated and saved.

It has been said, that when money is wanted for defraying public expenses; it makes no difference whether it is obtained by diverting the *sinking fund*, or by a new loan. There cannot be a worse fallacy than this. Money in a *sinking fund*, if never alienated, is improved at compound interest; but, when procured by a loan, bears only simple interest. A nation, therefore, whenever it applies the income of such a fund to current expenses rather than the redemption of its debts, chuses to lose the benefit of compound interest in order to avoid paying simple interest; and the loss in this case is equal to the difference between the increase of money at compound and simple interest. The following calculation will shew what this difference is.

One penny put out at our Saviour's birth to five per cent. compound interest, would, before the present year 1779, have increased to a greater sum than would be contained in a hundred and fifty millions of earth, all solid gold. But, if put out to simple interest, it would, in the same time, have amounted to no more than seven shillings and six pence. All governments that alienate funds destined for reimbursements, chuse to improve money in the last rather than the first of these ways. See, on the subject of this article, Dr. Price's Appeal to the Public on the Subject of the National Debt. Also his Observations on Reverendary Payments, &c. chap. iii. And additional Observations on Civil Liberty, part iii.

F U N

FUNDAMENT, the anus or aperture, through which an animal voids his excrements.

FUNDAMENTAL, something that serves as a base, cell, support, or foundation, for any thing.

The apostles creed contains the *fundamental* points of religion.

The Salic law is the *fundamental* law of the polity of France.

FUNDAMENTAL, in *Music*, denotes the principal note of a song or composition, to which all the rest are in some measure adapted, and by which they are swayed; called also the **KEY** of the song.

FUNDAMENTAL *basis*, is that which is formed only of the *fundamental* sounds of HARMONY, in such a manner, that in every concord it leads us to perceive the true *fundamental* found of that concord; whence it appears that it can have no other contexture than that of the *fundamental* succession of the harmony. The *fundamental* sounds are the octave above the principal found, the twelfth and the seventeenth major above the same found. In order to understant the nature of the *fundamental* *basis*, it is necessary to know, that every concord, though composed of many sounds, has only one found which is *fundamental*, viz. that which has produced that concord, and which serves for its *basis*. But the *basis*, which prevails below all the other parts, does not always express the *fundamental* sounds of the concords; for all of the sounds of a concord, we are at liberty to transfer to the *basis* that which we think preferable, with regard to the movement of this *basis*, or the inflection of the tune, or the nature of the instrument. In this case, the true *fundamental* found, instead of being in its natural place, which is the *basis*, is transferred to the other parts, or not expressed at all; and such a concord is called a *reversed* concord. See REVERSED.

In reality, there is no difference between a *reversed concord* and the direct concord by which it is produced; for the founds are always the same; but these founds forming different combinations, the combinations resulting from them have for a long while been considered as so many *fundamental concords*, and distinguished by different names. M. Rameau has shewn, in his *Traité de l'Harmonie*, that many of these pretended concords are only different modifications and alterations of a single concord: thus, the concord of the sixth is only a perfect concord, the third of which is transferred to the bass; in which, by introducing the fifth, we shall have another concord of the sixth and fourth. Here, then, are three combinations of a concord which has but three founds; those that have four are capable of four combinations; for each of the founds may be transferred to the bass. But if below this another bass be introduced, which, in all the combinations of the same concord, always affords the *fundamental found*, it is evident that the number of the consonant concords is reduced to three, and that of the dissonant to four; to which, if we add all the concords of the *Fourth*, *Fifth*, *Sixth*, and *Seventh*, we shall be brought to the same *fundamentals*; we shall find harmony simplified to a degree which could never have been expected, confounding the state of confusion in which M. Rameau found the rules relating to this part of music. It is certainly, as this author observes, very alienating, that persons have been able to advance the art to its present pitch of perfection, without knowing its foundation, and to propose all its rules with such exactness, without having discovered the principles on which they depend. The movement of the *fundamental bass* is regulated by the laws of harmonic succession, in such a manner, that if this bass deviates from the order which is prescribed, there is a fault in the harmony. With skill to regulate and observe the connection between the several founds that are united together, are the two most important rules relating to the *fundamental bass*; and the principal mechanical rule which is suggested by it, is to let the *fundamental bass* proceed only by consonant intervals, except when the cadence is broken; i. e. when the *fundamental bass*, instead of ascending from the fourth, after a concord of the seventh, as in a perfect cadence, ascends only by one degree, or after a concord of the seventh diminished, which affords a dissonance. As for the diatonic descent, this movement is not allowed in the *fundamental bass*, or at most only in the case of two perfect concords separated by a rest or pause, either expressed or understood. This rule admits no other exception. M. Rameau, indeed, has made the *fundamental bass* descend diatonically, for particular reasons, in the concords of the seventh.

The *fundamental bass*, whenever it is justly formed, consists either of perfect concords with consonant movements, without which these concords could have no proper connection, or dissonant concords in the *cells of cadence*, which always result from two *fundamental sounds*,

F U N

one of which precedes, and the other terminates the evidence. In every other case, the dissonance can not be well placed, nor rightly preserved. Hence it follows, that the *fundamental* bass can never proceed but in one of these three ways: 1. By ascending or descending from the third or from the sixth; 2. From the fourth or the fifth; or, 3. By ascending diatonically, by means of the dissonance that forms the connection, or by particular licence, above the perfect concord. Every other movement of the *fundamental* bass is faulty.

Although the *fundamenta* be right, in general, to be below the *thorough*-pass, there are, however, cases in which the *latter* is below the *former*; such are those of *canon* by *SUPPOSITION*, so called, because the *thorough*-bass supposes below the *concord* a new *found* which does not belong to that *concord*, which exceeds its limits, and is, therefore, below the *fundamental* *bass*.

The *fundamental* basis, the sole intention of which is to serve as a proof or tell of the harmony, is suppressed in the execution. where it would have a very bad effect: producing, at least, a very tedious monotony by the frequent return of the same concord, which are more agreeably disguised and varied, by its different combinations, in the thorough-bass. It may be added, in general, that the indispensable rules of the *fundamental* basis may be reduced to the three following.

1. There ought always to be at least a common sound in the harmony of two successive *fundamental* sounds. 2. In every *DOMINANT*, the *dissonance* ought to be so managed, that the dominant may not become *TONIC*. 3. Every dominant ought to descend from the fifth, and every *sub-dominant* ought to ascend from the fifth.

But besides it may be observed, that the *fundamental* bass is sometimes irregular; and in the number of its irregularities we may reckon the concords of the seventh diminished, and the broken cadences. The thorough-bass only the *fundamental* bass reversed for the false melody; so that when the *fundamental* bass is composed, the thorough-bass may be had by *reversing* or the *concords*. Thus, e. g. This *fundamental* bass is one found, *as follows*, *fa sol fa sol fa sol fa sol fa sol fa sol*. The thorough-bass will be made conformable to the *fundamental*, when it applies the *concords*, or is terminated *so*. Here, the *fa* admits also concords by *suppression*. Every note in the thorough-bass, which bears the concord of the false *FIFTH*, ought to rise diatonically; and every note which bears the concord of the *TRITH* ought to descend diatonically. The knowledge of the *fa sol fa sol* bass, or the rule for finding the *fundamental* bass of a given tune, depends much upon this. The *mode* of

FUNDAMENTAL *concordi* are of three kinds; viz. the perfect concord, the concord of the sixth, and the concord of the seventh. The first or perfect concord, is greater than the second, and the second is greater than the third. The second is of three sorts: in the two first sorts, the *SIXTH* is always greater, and the third greater or less, as the mode is greater or less. These two *concordi* differ only by their third. Between these two there is another concord, which on many occasions produces a very good effect, and is particularly used by the Italians; whence it is called the concord of the superfluous fifth, or of the Italian fifth. It is composed of a greater third, or superfluous fourth, or *TRITONE*, and a greater third, as *fa la si re* &c. There are several kinds of the *fundamental* SEVEN: the first is formed of a greater third, and two lesser thirds, as *fa si re fa*; the second is formed of a lesser third, a greater third, and a lesser third, as *re fa fa*; the third is formed of a lesser third, a greater third, and a lesser third, as *re fa fa*; the fourth is formed of one greater third, one lesser, and one greater, as *ut re fa*; the fifth is called the concord of the diminished fifth, and formed of three lesser thirds, as *ut re fa*. Encyclopædie, art. *Accordi FUNDAMENTALI*.

FUNDAMENTO, in the *Italian Music*, is in general every part that plays or sings the bass; but the thorough-bass is more particularly so called, because it is the basis or foundation of all harmony.

FUNDUCLA, an Egyptian coin, a sort of sequin, of the value of a hundred and forty-six medians. Pococke's Egypt, p. 125.

FUNDULUS, in *Ichthyology*, a name used by many for the small fish, called by others *COPIPER*, and by the generality of people in England, the *LOACH*.

FUNDULUS is used also by Schonevelds, and some others, to express the common gudgeon. The confusion of calling two fish by the same name, which is peculiarly appropriated to neither, is very evident in this and numerous other instances; but it is always to be avoided by using expressive and genuine names. Thus even the word gobic, the common name of the gudgeon, con-

found that fish with another very different genus; and Aræti is greatly to be applauded, who has found that our common gudgeon is no peculiar genus of fish at all, but is a species of the cyprinus. As such he has given it the proper specific name of the five inch spotted cyprinus, with the lower jaw shorter than the upper, and with two cirri or beards at the mouth; under this name the species is always to be known at sight, and can never be confounded with any other genus.

FUNERAL, the ceremonies performed at an interment; or the last offices paid to the deceased. See BURIAL. The word is formed of the Latin *funus*, and that of *funalia*, on account of the torches (which were *funus*, *etia circumdatis*) used in the funerals of the Romans; though others derive *funus* from the Greek *φύος*, death, or slaughter.

The first persons who seem to have paid any particular respect to their dead were the Egyptians, who erected monuments for transmitting the remembrance of their virtues to future ages. See PYRAMID.

Whenever a person died among the Egyptians, his parents and friends put on mournful habits, and abstained from all banquets and entertainments. This MOURNING lasted from forty to seventy days, during which time they embalmed the body. See EMBALMING.

When this ceremony was finished, the embalmed body was restored to the parents, who placed it in a kind of open chest, which was preserved either in their houses, or in the sepulchres of their ancestors. Before the dead were allowed to be deposited in the tomb, they underwent a solemn judgment, which extended even to their kings; and if the issue of the judgment proved unfavourable, they were deprived of the rites of burial; and this custom seems to have been practised among the Israelites; for we read, that their wicked kings were not interred in the sepulchres of their ancestors.

The funeral rites among the ancient Romans were very numerous. The deceased was kept seven days; and every day washed with hot water, and sometimes with oil, that, in case he were only in a slumber, he might be thus waked; and every now and then his friends meeting, made a horrid outcry or shout, with the same view; which distraction they called *conclamatio*.

The third conclamation was on the seventh day; when, if no signs of life appeared, the deceased was dressed and embalmed by the public slaves; placed in a bed near the door, with his face and head towards the street; and the outside of the gate, if the deceased were of condition, was garnished with cypress branches.

In the course of these seven days, an altar was raised near his bed-side, called *acerra*; on which his friends every day offered incense; and the libitinarii provided things for the funeral.

On the seventh day a crier was sent about the city to invite the people to the solemnization of the funeral in these words: *Exequias L. Tit. L. filii, quibus est commendatum ire, jam tempus est. Ollus (i. e. ille) ex adibus effertur*.

The people being assembled, the last conclamation ended, and the bed was covered with purple; a trumpeter marched forth, followed by old women, called *præfatae*, singing songs in praise of the deceased; and lastly, the bed followed, borne by the next relations. And if the person were of quality and office, the waxen images of all his predecessors were carried before him on poles.

The bed was followed by his children, kindred, &c. *ut ita*, or in mourning; from which act of following the corpse, these funeral rites were called *exsequia*.

The body thus brought to the rostra, the next of kin *laudabat defunctum pro reposita*, made a funeral oration in his praise, and that of his ancestors.

This done, the body was carried to the *pyra*, or funeral pile, and there burnt: his friends first cutting off a finger, to be buried with a second solemnity.

The body consumed, the ashes were gathered, and the priest sprinkling the company three times with clean water, the eldest of the *præfatae* crying aloud, *ulise*, dismissed the people, who took their leave of the deceased in this form, *Salve, vult, vult: nos te oratione quo natura permisit persequamur*.

The ashes, inclosed in an urn, were laid in the sepulchre, or tomb. The first Romans did not burn their dead, but interred them, as we do. Pliny, lib. vii. cap. 54, assures us, that the custom of burning was not introduced till after they had learnt that their enemies dug up, and exposed, the bodies of their soldiers buried in remote countries. And yet Plutarch, in his Life of Numa, observes, that Numa was buried; as having expressly forbid them by his testament to burn him: this shews that the Romans had practised burning before his time.

This custom of burning the dead, so religiously observed by the Greeks and Romans, was held in abhorrence by several other nations.

VOL. II. N° 144.

Herodotus relates, that the Persians detested it, as holding fire to be a god. The Egyptians declined to burn their dead, as taking fire for an inanimate baft, and judging it impious to commit the bodies of the deceased to be devoured by beasts. The custom of burning among the Romans ceased under the empire of the Antonines. See ROMANO and MOURNING.

In the Romish church, when a person is dead, they wash the body, and put a crucifix in its hand. At its feet stands a vessel of holy water, that they who come in may sprinkle both themselves and the deceased. In the mean time some priest walks by the corpse, and prays for the deceased till it is laid in the earth. In the funeral procession the exercit walks first, carrying the holy water; next the cross-bearer, afterwards the rest of the clergy, and last of all the officiating priest. They sing the *missa*, and some of the Psalms; and at the end of each Psalm, a *requiem*. We learn from Ale's ritual, that the faces of deceased laymen must be turned towards the altar, when they are placed in the church; and those of the clergy towards the people. The corpse is placed in the church, surrounded with lighted tapers; after this office for the dead, *missa* is said; then the officiating priest sprinkles the corpse thrice with holy water, and as often throws incense on it. The body being laid in the grave, the friends and relations sprinkle the grave with holy water.

FUNERAL charges, are not allowable against a creditor, except for the coffin, ringing the bell, parson, clerk, and bearer's fees; but not for the pall and ornaments. See DEBT.

FUNERAL column. See FUNERAL COLUMN.

FUNERAL games, *ludi funebres*, were a part of the ceremony of the ancient funerals.

They consisted chiefly in processions, and sometimes in mortal combats of gladiators around the funeral pile.

The custom was very ancient; though it had not always been the same. At first, they cut the throats of a number of captives before the pyra, as victims to appease the manes of the deceased. This Achilles does in Homer, *Iliad* 9, at the funeral of Patroclus; and *Æneas*, in Virgil, lib. ix, at that of Pallus, son of Evander. Cæsar, in his Commentaries, lib. viii. relates, that the Gauls also did the like.

But as length it appeared barbarous, thus to butcher men; and therefore to save the horror of the spectacle, they made the poor captives fight and kill one another, only saving some few of such as came off victors.

This custom was borrowed from the Greeks by the Romans; among whom the cruel diversion was called *munus*.

The first who introduced it at Rome was Junius Brutus, at the obsequies of his father's; or, according to others, Ap. Claudius, and M. Fulvius, during their consulate. The like horrible combats were also occasionally exhibited by the magistrates; and sometimes they were added to the theatrical pieces.

The emperor Claudius decreed, that whereas these accursed games were till then frequent and arbitrary; it should be the practice for the future only to perform them regularly every year at the expence of the state; and that the sodies should have the care and direction thereof. But he conceived a horror for them himself, and soon after abolished them; though it was still allowed particular persons to have them, provided they were worth forty thousand sesterces pro annum. They were not finally abolished before the time of Theodoric king of the Goths, at the end of the fifth century.

FUNERAL honours. See HONOURS.

FUNERAL oration, or *sermon*, a discourse pronounced in praise of a person deceased, at the ceremony of his funeral.

The custom of making funeral orations is very ancient. The Romans had it of a long standing; and it was always one of the nearest relations that made the harangue. Augustus did the office to his grandmother Julia, when only twelve years of age. Suet. Aug. cap. 8. And we have divers parallel instances.

The custom seems to have begun with the republic; at least, the first funeral oration we read of, was that of Brutus, who expelled the kings, and was the first consul; who, having been killed in a battle against the Hetrurians, *laudabatur pro reposita*, was praised in the forum by Valerius Publicola his colleague.

Indeed, some authors will have the practice more ancient. They maintain it to have been in use among the Greeks; and that Solon, who, according to Aulus Gellius, gave laws to the Athenians, in the time when the elder Tarquin reigned in Rome, was the first author thereof; something like which, it seems, the orator Anaximenes has left in writing. See Polydore Virgil De Invent. Rer. lib. iii. cap. 10.

FUNGIFER *lapis*, the *mystrum-bearing stone*, a name given by authors to a coarse stone found in Italy, and many other places lying near the surface of the earth, which they say will at any time produce *mystrum*, on being moistened with warm water.

FUNGITE, in *Natural History*, a name given by authors to a species of sea-coral, often found adhering to sea-shells, or to the larger corals in its recent state, and very often found also fossil, or buried at great depths in the earth; they are usually immersed in stone, and sometimes in clay. The more frequent of these are of a conic shape; sometimes they are flattened and discoid, and usually striated longitudinally; they sometimes are found in their fossil state adhering to shells or corals, but more usually separate. To this and some other bodies of this kind, Mr. Lloyd has given the name *columella*; to one of them that of *branchella*, from its resembling the gills of a fish; and to another, that of *undulata*, from its undulated figure.

FUNGODES, *hojard-mushroom*, in *Botany*, the name of a genus of plants, the characters of which are the same with those of the fungus, from which it differs only in being of a hollowed form, resembling a cup or empty open box. See *CLAVARIA*, *ELVELA*, and *PALLIA*.

FUNGOUS *febb*, is a spongy excrecence, or (as we popularly call it) *spread lebb*, frequently growing on the lips of wounds, ulcers, &c.

The *farsetis* is the effect of a sort of *Fungus* febb. In ulcers, Wiseman observes, they frequently arise a spongy, or *fungus* febb, either from the too great afflux of humours, or through the surgeon's unskilfulness. It must be suppressed, or taken off by drying medicines, or even by caustics; as lapis tutia, burnt alum, precipitate of mercury, Roman vitriol, &c.

FUNGUS tumori. See *TUMOR*.

FUNGUS, in *Natural History*. See *MUSHROOM*.

FUNGUS, in *Surgery*, a fleshy *TUMOR*, or excrecence, very spongy, soft, and pale; arising on the membranes, tendons, and other nervous parts, in consequence of ulcers, wounds, contusions, and strains.

Fungus is frequently formed on the meninges, or membranes of the brain, in wounds of the head when not well covered, or defended from the external air: they are also frequent about the joints; which last grow very insensibly.

But where the skin is open, finding more room, they grow to a prodigious degree in a very little time, assuming the form of a mushroom, or *fungus*.

There are also *fungus* of the anus, and uterus. They are all supposed to proceed from a retention and depravation of the nutritious juice.

The *fungus* is a general kind of excrecence, whereas there are divers particular species: as the *ficus*, the *farcoma*, *condyloma*, &c.

FUNGUS of the brain. Mr. Quefney assures us, that spirits are not so proper for preventing the growth of *fungus* from the brain, as balsam florivatus, or oleum terebinth. Mem. de l'Acad. de Chirurg. tom. i.

FUNGUS, in *Mineralogy*, a name given by Dr. Lister, to a blackish bituminous substance, found in some of the mines of Derbyshire. It adheres to the sides of the fissures of rocks, and lies in seams of the strata. It is of a blackish colour and fatty substance, which never dries in the air, but always remains as moist as when taken out of the mine. Some masses of it are soft and like a jelly, others are hard and firm, and in these there are several lumps of pure bitumen in many parts. This is inflammable like resin. It is light, but breaks finer, and shines like good aloes when fresh broken, but that it is a little darker coloured, and has some tinge of purple in it. In some pieces the purple is wanting, and there is a green in the place of it. On being distilled, it yields first a limpid and insipid water, then a whitish water of a strong taste, and finally a yellow and clear oil, much resembling oil of amber, but the process affords no volatile salt in the neck of the receiver, in which it differs from *AMBER* when treated in the same manner. Phil. Trans. N° 6.

FUNGUS oculi, a name given by some of the writers on the diseases of horses to a distemper of the eye, to which that animal alone is subject. The first author who has communicated an observation of this disorder to the world is Dr. Lower, in the Philosophical Transactions. He observes, that horses alone are subject to it, and calls it a spongy excrecence of the uvea; it is commonly of a dark milk-colour, and grows out of the edge of the uvea, and though of little consequence in its first stages, yet if it grows very large, or if the number of the *fungus* increase, it weakens and obstructs the creature's sight, and sometimes wholly takes it away. The uvea is a muscular part, and its chief use is to dilate or contract itself in a proper manner for the admission of objects with as much light as the eye can bear, so that the brighter the light is,

to which the eye is exposed, the more this membrane is contracted into a narrow compass, and the more dark the place is, the more the opening is dilated. This sudden change, and the office of this part, may be more conveniently seen in the eye of a cat, than in that of any other animal, but it is the same in all, in a greater or less degree. If the edge of this coat be loaded with a very large excrecence of this kind, or if several, though smaller, grow all round it, it must necessarily happen, that the pupil, or sight, is very much if not totally obstructed, and the animal sees very little, or not at all. The horses of this kind are very ill furnished for seeing in the sunshine, but do very well in dark days, or in the dusk of the morning or evening, when the disease is not too violent. It is observable, that when these *fungus* grow in the eyes of young horses, they become much smaller, when they are taken to dry meat in the stable, and increase again when they are turned out to grass. Whether this be owing to the difference of dry and moist food, is not easy to determine, but it is most probably owing to the difference of pasture: the horse at grass, being obliged to carry its head much lower than those which feed in the stable. Those *fungus* that are fixed on the upper part of the uvea, are apt to grow the largest, and to hinder the sight most; and those which grow in the middle of the uvea, hinder the sight more by obstructing the objects, than those which grow in either corner or angle of it. The cure is not easy; all that can be attempted must be by dry diet, and attenuating medicines; and a palliative remedy may be the hanging something over to shade the eye, and keeping it from being exposed nakedly to the sun, the consequence of which will be, that the pupil will not be so closely contracted, and consequently the light not so much obstructed. Phil. Trans. N° 32.

FUNICULUS umbilicalis. See *UMBILICALIS*.

FUNNEL of a chimney, the flue, or smallest part, of the chimney, from the waist upwards.

Palladio orders, that the *funnel* be raised three, four, or five, feet at least, above the roof, that it may carry the smoke clear from the house into the air.

Care, too, is to be taken, as to the width; because, if it be too wide, the wind will drive back the smoke into the room; and if too narrow, the smoke will not be able to make its way. Chamber-chimneys, therefore, are not to be made narrower than ten or eleven inches, nor broader than fifteen. See *CHIMNEY*.

FUNNEL fashioned flowers. See *INFUNDIBULIFORM FLOWERS*.

FUNNEL ships. See *POLYPS*.

FUR, in *Commerce*, &c. See *FURS*.

FURBISHER, a person who furbereth, or polishes arms, and gives them a brightness and lustre.

In the general sense of the word, it includes what we now call *armourers* and *sword cutlers*; in a more restrained sense, it is appropriated to those who clean, and scour up old swords, guns, and halberds, and put them in order.

Among the officers of the Tower, there is a *furber* of small arms, another of swords, and the like there is in most other armories of England; or at St. James's, Windsor, Chelster, Plymouth, Hull, and Berwick.

FURBISHING, the act of cleaning, scouring, and polishing, arms; as guns, pistols, swords, &c.

The word is formed of the French *fourbisseur*, which Hicks derives from *furber*, which in the language of the ancient Franks signified to clean and polish; though M. Huet chooses rather to derive the French *fourbir*, and *fourbisseur*, from the English *furish* and *furishing*. Skinner observes, that some authors derive the English *furish* from the Latin *furvus*, and *furber*; but for his part, he rather derives it from the German *farb*, colour; and *furber*, to dye, or give a colour.

Furishing is principally performed with emery.

FURCA, *FORK*, in *Antiquity*, a kind of punishment, or rather an instrument of punishment, among the Romans.

The form of the Roman *furca* is very obscurely described by the ancients, and much controverted by the moderns. All we know for certain is, that it was of wood, and resembled a fork; whence it is called, in writers, *furca*, *furca*, *furca*, *furca*, that is, *furca duplex*, *furca*, *furca*, *furca*; a double forked, or horned timber. Plinius, treating of the *furca*, says, it is originally the piece of timber wherewith the beam of the wagon is upheld; he adds, that it is the same with what the Greeks call *apophyses*, and *sternima*; and the *sternima* is described, by Hesychius, as the forked piece of timber put under the yoke of the wagon.

From these accounts, Godwyn takes the *furca* to have been the beam of a wagon, to which the yokes are fastened.

The punishment of the *furca* was of three kinds; the first, only *ignominiosa*, was when a matter forced his servant, for small offences, to carry a *furca*, or fork, on his shoulders,

ders, about the city; confessing his fault, and warning others to beware of the like: whence such servants come to be denominated *forisfacti*.

The second kind was *penalis*, when the party, having the *forca* on his neck, was led about the circus, or other place, and whipped all the way.

The third was *capitalis*, the malefactor having his head fastened to the *forca*, and so being whipped to death.

In after-times of the empire, when this sort of punishment became interdicted, the form of the *forca* was changed, and made like our GIBBET, or gallows. See CROSS, &c.

FORCA & *flagellum*, in our old writers, denotes the meanest of all servile tenures, when the bondman was at the disposal of his lord for life and limb. *Ipsi tenet in villis, necesse est furcam & flagellum de dominis suo, &c.*

FORCA and *fissa*, in our ancient customs, i. e. gallows and pit, denoted a right, or jurisdiction, of punishing felons; viz. men with hanging, women with drowning.

FURCHE, in *Heraldry*, a cross forked at the ends. See CROSS.

FURCULA, in *Anatomy*, the same with CLAVICULA.

FURFUR literally signifies *bran*; and is therefore used for the scales, scurf, or dandruff, which grow upon the skin; having some likeness thereto. See CUTICULA.

FURFURATION, the falling off of *furfur*, in combing, &c.

FURIA, in the *Italian Mufe*, is used for a very quick and strong manner of singing or playing.

FURIAN Law, in *Roman Antiquity*, a testamentary law, so called from C. Furius, the tribune, by whose interest it was enacted. This law forbade any Roman citizen to leave by legacy above the value of one thousand asses to any one person, and at the same time condemned the legatee to pay four times the sum which was given him above what the law stipulated. See VOCOMIAN Law.

FURIES, *Erumenides*, *Dire*, in the *Heathen Theology*, and *Poetry*, were infernal deities, supposed to be the dispensers of the divine vengeance, the punishers of wicked actions both here and hereafter, and the insidious of terrors, wars, and pestilence.

The *Furies* were reputed the ministers of Pluto, and the avengers of crimes. Strabo paints them clothed in long robes falling to their heels, but girt about the breast. They were three in number; TISIPHON, MEGARA, and ALECTO.

The poets speak of great numbers of *Furies*, some of whom were employed in tormenting criminals in Tartarus, and others wandering over the earth to tempt, or to punish the wicked here. Thus Virgil speaks of the

—*agmina sacra ferorum.* *Æn.* vi. ver. 571.

But the three, above named, were supposed to exceed all the rest in cruelty and malice, and the power of doing mischief, and are called, by way of eminence, the *Furies*, and sometimes the *Dire*, a name peculiar to these three. They were three sisters, and born at one birth of the goddesses of night.

Patru, Spanheim, &c. will have it to be those which we see on a medal of the emperor Philip, struck at Antioch, on whose reverse are represented three women dressed as above mentioned, and armed with a key, and burning torches, poniards, and serpents.

Struvius, *Antiq. Rom. Synt.* cap. l. p. 182, adds, that the three *Furies* may probably be no other than the triple Hecate, whom the ancients believed to pursue and torment the wicked in hell, on earth, and in heaven.

Some of the poets add a fourth *Fury*, called *Lysa*, a Greek word, signifying madness, or rage.

They represent the *Furies* as old, squallid, and meagre, with pale cheeks having a kind of feverish flush on them, with eyes inflamed, their heads twisted round with snakes, and furnished with whips and burning torches in their hands, to punish the guilty.

The dissonant was sacred to the *Furies*, and such as offered sacrifices to them were crowned therewith. This we learn from Eustathius, on the first book of the *Iliad*, p. 57.

The *Furies* were also called *Pænes*, *Manes*, on account of the punishments they inflicted on criminals; as their denomination *Furies* arose from the rage and madness which they threw into the conscience. Voss. *De Idolol.* lib. viii. cap. 18.

The Greeks called them *Erumenides*; the origin of which name is much controverted among the learned. The etymology that seems best authorized, derives it from *erumen*, *evil*, *mild*; which was applied to them on occasion of Orestes's being absolved of the murder committed by him on the person of his mother. *Micæra*, it seems, appealed and pacified the *Furies*, so that they ceased to pursue him; upon which the Athenians ever after denominated them *Erumenides*.

But it must be observed, that, in truth, the Athenians called them by the same name long before Orestes's time, as appears from the *Œdipus* of Sophocles. There was a temple in Athens, near the Areopagus, consecrated to the *Erumenides*, whom the Athenians called *terrenalis goddesses*: Aristides, and the scholiast of Thucydides, speak of this temple as erected in memory of the judgment of Orestes.

FURIGELDUM, in our old writers, a mulct paid for theft. **FURINALIA**, in *Mythology*, feasts instituted in honour of *Furina*, the goddess of robbers among the Romans. They were celebrated on the sixth day before the calends of September. The goddess *Furina* had a Temple at Rome, and a priest called *flamen Furinalis*. Cicero represents this goddess as the same with the *Furies*; and Turnebus, in his *Adversus*, defends this opinion, alleging that Plutarch, in speaking of the wood, consecrated to *Furina*, where the younger Gracchus was killed, called it the wood of the *Erumenides*, or of the *FURIES*.

FURLING lines are small lines made fast to the top-falls, top-gallant-falls, and the mizen-yard-arm; serving to fast up those falls, i. e. to wrap and bind them up close to the yard. The mizen has but one *furling* line, but all the rest have two, one at each end. Those that are used for the larger falls are generally flat, and are known by the name of galkets.

FURLONG, an English long measure, containing the eighth part of a mile.

The English *furlong* is equal to forty poles or perches, and the perch to 16½ feet. Though in an old law-book, printed in Henry the VIIIth's time, we read, that six hundred feet, of five score to the hundred, make a *furlong*.

In Scotland the *furlong* is equal to forty FATHOMS. Hercules is said to have run a stadium, at *furlong* at one breath.

FURLONG is also used for the eighth part of an acre, or half a rood.

FURLONG is sometimes also used for a piece of land of more or less acres.

FURLOUGH, in *Military Language, a licence granted by an officer to a soldier to be absent for some time from his duty. See DESERTERS.*

FURNACE, an utensil, or vessel, proper to contain fire, or to raise and maintain a vehement fire in, whether of coal or wood.

There are divers kinds of *furnaces*, of various forms, and for various uses.

The domestic *furnace*, used in making confections, &c. is usually of iron, or earth.

Those used by the goldsmiths, refiners, &c. are much larger, and of a different structure.

Those wherein lime, bricks, &c. are burnt, are called *kilns*.

FURNACE is particularly used for a kind of oven, wherein the ores of metals, after heating, washing, &c. are melted down by a great coal or wood fire.

The structure and application of these *furnaces* are somewhat different, for the different metals.

Swedenborg has laid down, from his own experience, certain rules for the general construction of these *metal-lurgical furnaces*, by which they will always be made more advantageous to the proprietor, certain paribus, than any other kind. These rules are, that the chimney be always placed as nearly as may be, behind the centre of the *furnace*; that the smaller the depth of the fire-place, provided it be sufficient to hold the coals, the better; that all *furnaces* must be the better, the wider they are forwards, and the higher they are, so as not to lose the benefit of reverberation.

FURNACE is more strictly applied to those used in the melting of iron, which authors frequently confound with iron forges, though there is a considerable difference between them.

This *furnace* is a brick structure, much in the shape of an egg set on end, wherein the iron ore, after it has been burnt in a kiln, is put, intermixed with cinders and charcoal, and the whole melted, till it trickle down in a receiver underneath; where the scum and dross being taken away, the metal is thrown into furrows made in a bed of sand, and thus is cast into fows or pigs of iron.

The forge is a place where the pigs are heated, and fused a second, and even a third time, to prepare and fit them farther for use. See FORGE and IRON.

These *furnaces*, as they are employed in running the most difficult of fusion of all metals, so they are of all others contrived the largest, and capable of carrying heat to the greatest degree. When they are to be used, they are first

first filled up to the top with coals; and the lower part being lighted, the top, and all other parts of the furnace, where the air could have passage, are closed firmly up with iron plates laid one over another. The consequence of this is, that the fire is put out, and the whole is kept in this state ten or twelve days. At the end of this time the furnace is opened, and the coals are found all black, without a single spark of fire in any part, yet extremely hot, and reduced to a tenth part of their quantity. When the furnace has been thus opened about a quarter of an hour, the matter begins to take fire of itself by the mere contact of the air. The first appearance of this is very remarkable; there arises a very bright flame from some of the coals, which plays about their surface, and spreads itself from one to another, without the appearance of the least spark of fire in any part of any of the coals. The ore of the iron is for the first day put only in the middle of the furnace, and that but in small quantity; the next day more, and every day afterwards more and more is put on, and by degrees it is spread over the whole surface of the furnace to the edges. This is the method of working the ore to the utmost advantage, and with the most dispatch. The whole process for one furnace of ore is finished in about eight days from the time of the opening top; all the ore of the first quantity of coal, is only thoroughly to warm the sides and walls of the furnace; and it is after this to be kept carefully supplied with fuel, and the ore only spread out towards the sides as the extreme heat, most sensible in the centre, increases. If too much be laid on of the ore at first, there is always a loss from the quantity of metal. The quantity of the coals necessary to any given quantity of ore, differs in proportion to the advantageous or faulty structure of the furnace. In the very best constructed ones, the weight of the coals and of the ore need be no more than equal. The flame which makes its way out of the bottom of the furnace is of different colours, according to the nature of the ore and of the coals; sometimes red, sometimes yellow, and sometimes green. That which issues out from the top of the furnace is of a red colour, and ascends in a sort of spiral line, resembling the sound of distant falls of water as it mounts up. With all the care that can be taken to heat the sides of the furnace, and to keep them hot, the middle is always much the hottest, and the ore soonest runs into metal there. Swedenborg de Ferro & Igne.

FURNACE, in Chemistry, is a receptacle either of brick, iron, stone, or clay, wherein the fire, necessary for the several operations, is contained, determined, and directed.

The furnace consists of several parts: as a place for the vessel or body to be wrought on; a hearth, or hole for the ashes; a chimney; a grate; a door; a dome; and a fan, or else registers, whereby to let in air, to increase or abate the fire.

The perfection of a furnace consists in its maintaining a constant, equitable fire; and this easily tempered, and at an easy expense.

To have the expense easy, the whole action of the fire, or fuel, must be employed on the subject that is to undergo the operation.

It must be equable, since different degrees of fire have different effects: so that if any given degree would answer any given intention, an alteration of that degree will prevent the intention from taking place. And on these circumstances does all the variety of furnaces depend.

Furnaces are either fixed and immovable, called *athanors*; or portable, called *calabats*, i. e. universal, as being proper for all operations, where the body to be operated on is not too large.

The first species of *athanor*, or fixed furnace, is fitted to maintain an equal heat, and such as shall last a long time without addition of fresh fuel.

The second is the furnace of the *alambic Maria*, fit for the distillation of the more subtil spirits.

The third is the digesting furnace. See **DIGESTION**.

The fourth is the anemion, or wind furnace, called also melting furnace, and metallic furnace; used in the fusion of metals, minerals, and vitrifications.

It is called wind furnace, because the air drives forcibly in, to blow up the coals.

For an account of the principal furnaces used in chemical and other operations, see the following articles.

FURNACE, almond, or olivum. See **ALMOND**.

FURNACE, assaying, cupelling, or assay. (See Tab. III. Chemistry, fig. 37.) is made in the following manner: 1.

Make with iron plates a hollow quadrangular prism, eleven inches broad and nine inches high *a b*, ending at top in a hollow quadrangular pyramid *b c d*, *e f*, seven inches high, terminating in an aperture at top seven inches square. This prism must be closed at bot-

tom with another iron plate, which serves as a basis or bottom to it *a g*. 2. Near the bottom make a door *e*, three inches high, and five inches broad, that leads to the air-hole. 3. Above this door, and at the height of six inches from the basis, make another door *f*, of the figure of a segment of a circle, four inches broad at its basis, and three inches and a half high in the middle. 4. Then fasten three iron plates on the top of this furnace; let the first of them *g h* eleven inches long, and half an inch high, be fastened, so that its lower edge shall rest against the bottom of the furnace, with three or four rivets, and in such a manner, that there may be between the upper edge of the said plate and the side of the furnace a groove *i o* wide, as that the sliders of the lower door *e f* may be put into it, and freely move backwards and forward therein; these must be made of a thicker iron-plate. The second iron-plate *k l*, eleven inches long, three inches high, and perfectly parallel to the foregoing plate, must be fastened in the space between the two doors, in such manner, that both the upper and the lower edge of it may form a hollow groove with the side of the furnace. One of these grooves, which is turned downwards, serves to receive the upper edges of the sliders that the lower door *Nº 2*. The other, that turns upwards, is to receive the inferior edges of the sliders of the small door above, *Nº 3*. The third plate, *i h*, which is like the first, must be rivetted close above the upper door, in such manner, that it may form a groove turning downwards, and contiguous to the upper edge of the upper door, *Nº 3*. 5. In order to shut up both doors, *Nº 2* and *3*, you must adapt to each of them two sliders made of iron plates, that may move within the above mentioned grooves *k l*, *i h*; but the two sliders belonging to the upper door, *Nº 3*, must have each a hole near the top; that is, one a small hole one fifth part of an inch broad, and one inch and a half long *m*; and the other a semi-circular aperture one inch high and two inches broad *n*. Let, besides, each slider have a handle, that they may be laid hold of when they are to be moved. 6. Moreover, let five round holes, one each round, be bored in the furnace, two of which must be made in the fore part of the furnace *a g*, two others in the back part, all at the height of five inches from the bottom, but three inches and a half distant from each side of the furnace; and, finally, a fifth hole *p*, at the height of one inch above the upper edge of the upper door *f*. 7. In short, let the inside of the furnace be armed with iron-hooks, setting out half an inch, and about three inches distant from each other, to fasten the lute with which the furnace is to be covered over within. 8. Let then an iron, moveable, hollow, quadrangular pyramid *q*, three inches high, be adapted to the upper aperture *d* of the furnace, at the basis seven inches broad, ending upwards in a hollow tube *r*, three inches in diameter, two inches high, almost cylindrical, though somewhat convergent at top. This prominent tube serves to support a funnel or flue, which is almost cylindrical, hollow, made of iron-plates, and two feet high, and which, when a very strong fire is required, is put perpendicularly upon the shorter tube, in such manner, that it enters close into it, one inch and a half, or two inches deep, and may again be taken off at pleasure, when there is no need of so strong a fire. But this pyramidal cover *q* must besides have two handles *s s*, adapted to it, that it may be laid hold of, and thus be taken away or put on again: and that this, being put on the aperture *d* of the furnace, may not be easily thrown down, let an iron plate be rivetted to the right and left upper edge of the furnace *e f*, and be turned down towards the inside, so as to make a suture open before and behind, into which the lateral edges of the cover may enter and be fastened, and at pleasure be moved backwards and forwards, whenever it must be put on, or moved. 9. Let a square ledge, made of a thick iron-plate, be fastened at the top of the upper edge of the lower door *e*; this is designed to support the grate and the lute: but it must be made of two pieces, that it may be easily introduced into the cavity of the furnace. Thus you will have an assay-oven, which must afterwards be covered over on the inside with LUTE. This you are to do as follows: That the fire may be better confined, and that the iron may not be destroyed by growing red-hot, the whole inside of the furnace must be covered over with lute, one finger or one finger and a half thick. But, before you cover the inside of your furnace with this lute, you must first put within the furnace small iron bars, equal in length to the diameter of the oven, quadrangular, prismatical, half an inch thick, having their extremities supported by a square iron ledge, and three-fourths of an inch distant from each other; and you must fasten them so, that their flat sides may be oblique with regard

to the transverse section of the furnace, and that the two opposite angles may look one upwards and the other downwards; the bars must not be laid flat, but edge-ways, by which situation you hinder the ashes of the fuel of the fire from being detained too long between the interstices of the said iron-bars, and from making an obstruction that would oppose the free draught of the air. The furnace being then covered over with lute, and dried up by a gentle heat, is at last fit for decimallical operations, and especially for such as must be performed in the alaly-oven.

If then an operation is to be made in the furnace hitherto described, you must let through the four lower holes above described, of the furnace *a*, placed before and behind, and directly opposite to each other, two iron-bars one inch thick, and long enough that their extremities on every side may jut out of the holes a small matter. These serve to support the MUFFLE and its bottom. You then introduce the muffle through the upper aperture of the furnace *d*, and place it upon the above described iron-bars, in such manner, that the open fore-side of it be contiguous to the upward border of the upper door *f*. The fuel of the fire is introduced through the top of the furnace *d*, the cover of which, on this account, must be moveable, and not very heavy *g*. The best fuel for the fire is charcoal made of the hardest wood, especially of beech, broken into small pieces of the bigness of an inch, wherewith the muffle must be covered over some inches high. We then reject larger bits of coals, because they cannot fall through the narrow interstices, between the sides of the muffle and those of the furnace, and cannot of course sufficiently surround the circumference of the muffle. Whence it happens, that there are on every side places void of fuel, and the fire is either not strong enough or unequal. But if, on the contrary, you use coals too small, then a great part falls immediately through the interstices of the grate into the ash-hole; and the tenderest particles of them turn too soon into ashes, and by increasing the heap of ashes, obstruct the free draught of the air, which is here greatly requisite.

A perfect management of the fire is most commonly necessary in the performing of operations in this furnace; therefore the reader must give attention to what follows: If the door of the ash-hole *e* is quite open; and the sliders of the upper door *f* drawn towards each other, so as to touch one another in the middle of the door, and if, besides, the cover *g*, and the funnel adapted to its tube *r* is upon the top *q* of the furnace, the fire will be then in the highest degree possible; though, in the mean time, it is hardly ever necessary to put the funnel on, except in a very cold season: but if, after having disposed the furnace in the manner just described, you put red burning coals into the open upper door *f* of it, the fire is still more increased thereby: however, this artifice is never, or very seldom, necessary. When you shut the upper door with only that slider that has a narrow oblong hole in it *m*, then the heat becomes a little less; but it diminishes still more when you shut the door with the other slider that has in it the semi-circular hole *n*, which is larger than that of the first slider: nay, the heat again is less when you take away the funnel put at the top of the cover: finally, the door of the ash-hole being either in part or totally shut, the heat is still diminished, because the draught of the air, so necessary to excite the fire, is hereby hindered: but if, besides all these, you likewise open the upper door quite, then the cold air, rushing into the muffle, cools the bodies put under it: that air is to be changed, to a degree never required in any operation, and such as will entirely hinder the boiling of lead. If, during the operation, the fire begins to decay, or to grow unequal, it is a sign that there are places void of coals between the sides of the furnace and those of the muffle; therefore, in this case, you must stir your coals on every side with an iron rod, which is to be introduced through the upper hole *p* of the furnace, that they may fall together, and thus act in a proper manner and equally. See Cramer's Art of Assaying, by Dr. Mortimer, p. 75. See Portable FURNACES.

FURNACE, called *Athanas*, or *tower-furnace*, is represented in fig. 38. See *ATHANAS*. It is thus constructed. 1. Let a small square hollow tower *a a a* be formed of such stones, or of bricks made of Stourbridge clay, or Windsor loam, as may resist the fire; let the sides of it be six inches thick, and forming a square cavity within of ten inches on each side *b b b b*. The height of it is determined according as it is to keep up the fire long, without any addition of new fuel: five or six feet are most commonly sufficient. 2. At the bottom of this tower make an opening *c*, six inches broad, and as many inches high; hang to it an iron door, being on every side

one inch broader than the opening, and such as may shut it very close: for which purpose the external edge of this opening must be excavated all round in such a manner, that it may form a groove one inch broad, into which the edges of the door may be received. 3. At the distance of ten inches from the bottom of the tower, put a grate *d*, made of prismatical quadrangular iron bars, one inch thick, and three quarters of an inch distant from each other: let also each of these iron bars be so situated with regard to the tower, that the two opposite acute edges of each may look perpendicularly, one downward, the other upward, that, by this means, the ashes may easily fall into the ash-hole. 4. Make above this grate an opening circular at top *e*, six inches high, seven inches broad, that may, as well as the ash-hole, N° 2. be opened and shut with an iron door. 5. Adapt to the top of the tower an iron cover *f*, exceeding the aperture of the tower all around two inches, and having a handle, wherewith it may be easily taken away, and put on again. Thus you are to make the furnace called in Latin *furnus primarius*. 6. Then cut out in any side of the tower, for instance in the left, an oblong square aperture, going up obliquely towards the outside *g g*, four inches and a half high, ten inches broad, having its inward inferior edge one inch and a half, or two inches above the grate *d*; that by the intervening of this hole, the cavity of this tower may communicate with another immediately to be described. 7. Nearly over-against the same side of the tower, make a cavity with stones, whose inferior part must be a hollow prism *h h h h*, six inches high, twelve inches broad, ending at top in a semi-cylindrical arch *i i*, described by a radius of six inches; that by this means, the height of the whole cavity may be twelve inches in the middle. Let this anterior cavity be totally open, though when requisite, it is to be shut very close with an iron plate *k k*, whose inward surface is to be constructed in the same manner as is prescribed for the sliding door of the melting furnace, and then luted two inches thick within. Moreover, let there be in the middle of this plate, a round hole, four or five inches in diameter, and let the circumference of this hole have an iron cylindrical border made to it, and prominent within; that by means of it, the lining of lute within may be supported, and kept from falling down easily. Let a notch one inch broad, and two inches deep be made in the outward circuit of the aperture of this cavity, to receive the extremity of the plate that shuts the aperture. The hole of this plate either is shut with a stopple, or serves to pass the neck of the retort through. This plate likewise is fastened with two bolts *l l*, to be put perpendicularly with iron hooks *m m*, driven into the wall near the edge of the aperture, so that one bolt may fasten the upper part of the plate, and the other the lower. 8. It is moreover proper, that the square aperture *g g*, through which the fire enters from the tower into the cavity hitherto described, N° 7. may be shut and opened at pleasure with an iron slider: for if this is not done, an excessive fire, employed sometimes by an unexperienced hand, cannot be so easily checked. For this purpose, let a slit half an inch broad, and eleven inches long, be left in the wall that constitutes the upper part of the cavity N° 7. and is contiguous to the tower so that it may exceed the length of the square aperture *g g*, a small matter on every side, and reach before and behind into the small groove, going down along the perpendicular sides of the said aperture, *g g*, and retain the iron slider to be put into it to keep it steady. However, let this iron slider be six lines thick, eleven inches broad, and five inches high; and let a couple of small iron chains, *p p*, be fastened on each side of its upper edge, wherewith the slider may be lifted up and let down again. Therefore let a couple of strong iron nails be drove into the contiguous wall of the tower, perpendicularly over those places in which the said small chains are fastened to the iron slider, that any of the links of the chains may be suspended on them at pleasure. Moreover, let the upper edge of the slit above described be entirely that up with stones and cement, leaving only two small holes through which the small chains may be passed. On the left of this cavity (N° 7.) and at the distance of eight inches from the bottom of it, let a square, *q q q q*, chimney or funnel be erected with bricks, three inches and a half in the clear, four foot high, and a small matter convergent upwards, so that the diameter of it at top may be three inches. This funnel must be contrived to be shut closely with an iron slider, having a handle to it, *r r*, which slider must move freely between a double iron square frame fastened in the walls of the funnel, at such a height from the hearth as shall seem convenient to any artificer. 10. Below this chimney let a square aperture be made, like the foregoing

ing (N^o 6, *g, h*), leading obliquely up to the bottom of another cylindrical cavity, *s, s, s, s*, which is eight inches deep, described by a radius of six inches, open at top, and there converging inwardly into a border one inch thick, and six lines broad, designed to support an iron pot. Likewise, cut in the anterior wall of this cavity, and at the upper part of its mouth, a segment two inches and a half deep, five inches broad, and sloping forward, *v, v*, to receive the neck of the retort. 11. To this cavity (N^o 10.) belongs an iron pot, *w, w*, eleven inches broad, and about nine inches deep, which must be encompassed with an iron ring, *x, x*, one inch broad, and fastened at the distance of one inch and a half from the upper end of the pot. Let a segment, *y*, be likewise cut off the upper edge of this pot, which segment must be four inches and a half deep, and five inches broad; the iron ring just described must be bent all round the edges of this segment. 12. Overagainst the aperture, *z, z*, which communicates from the first cavity (N^o 7.) into the second (N^o 10.) let another such aperture, *a*, be made, two inches distant from the bottom of the second cavity (N^o 10.) perfectly like the foregoing, *g, g, h, h*, and communicating obliquely upwards with a third cavity, *i, i, i, i*, like and equal to the second cylindrical cavity, *s, s, s, s*, that the fire may pass from the latter into the former. 13. In the hinder part of the wall which makes the aperture just mentioned, *z*, let a chimney like the foregoing, *g, g, h, h*, and of the same height, *a, a, a, a*, be erected, which may be shut with a slider like that, *3, 3*. 14. Finally, on the left side of the third cavity let an aperture be made in the same manner, *d*, and like the foregoing ones, *g, g, h, h*, more remote however from the bottom of the cavity, without a passage at the other extremity and communicating only with the cavity of the third chimney, *i, i, i, i*, which must be erected in the same manner as the two foregoing ones, *g, g, h, h*, *z, z, a, a, d, d*. Thus you will have a furnace very proper for a great many operations.

We are now to speak of the use of the athanor just described; and chiefly to mention to what operations each of its parts serve in particular, and then how the fire may and must be governed in it. 1. You must put at the upper arch'd door, *e*, of the tower a semi-cylindrical muffle twelve inches long, which must be introduced through the door; for which this reason must be of the same height and breadth as that door, three quarters of an inch thick, and open behind, being shut there by the hinder part of the athanor, as far as which it must reach. For this purpose, a tile must be set upon the grate, *d*, to support the muffle. Let also this muffle have small pieces cut out near its base, as common assay muffles. You may put under this muffle your cement pots, or such bodies as must be calcined with a long and violent fire; which can be done without a muffle, though not so neatly. 2. In the first chamber, *b, b, b, b, i, i*, you may make the most violent distillations with an open fire; for retorts or large vessels are introduced into it, after you have taken away the door, *k, k, k*, and are put either upon the hearth itself of this chamber, or upon a particular support of stone. But you must place these vessels in such manner, that their necks may easily pass through the hole of the door, when put on again; for which purpose, they chule a support sometimes higher, sometimes lower, according to the different heights of the vessels. When afterwards the door is put on again; and fastened with both its bolts, *u, u*, you must close with lute all the chinks which lie open about the neck of the vessel, and between the edges of the door and the entrance of the chamber. Then you apply to the neck of the vessel a cylindrical segment, ten or more inches long; by means of which the heat and the boiling vapours coming forth are gradually diminished; left the recipient, which is always chosen a glass vessel, should split. The recipient, which must be united with the other office of the said segment, is supported either by the pavement, or by a certain kind of trivet, the construction of which is such, that it may be set higher or lower by means of three screws. 3. In this same chamber, instead of distillations, you may also make cementations, calcination, &c. in which case the round hole of the iron plate may be shut and again opened with a stopple, that one may view the inside. 4. The second and third cavities, *s, s, s, s, i, i, i, i*, serve chiefly to such operations as are made in bath (or beds) of sand, oil, or slugs. For instance, you put into each of the cavities a pot, *v, v*, and you stop with thin lute or with sand, which must previously be moistened, the slip between the iron ring, *x, x*, and the border of the cavity, upon which this ring rests. 5. Besides, you may also make, in these two cavities distillations by a reverberating fire, as well as in the first; only the fire is left violent in these, though sufficient to extract aqua fortis-

You then take out the iron pot, *v, v*, and inverting it, you put it upon the mouth of the chamber; so that the brim of the pot, being the depth of one inch and a half above the iron ring *x, x*, wherewith this pot is surrounded, may be received within the mouth of the cavity, and so that the segment cut in the pot may, together with the segment cut out from the side of the cavity *v, v*, form a hole to let the neck of the vessel through. 6. All the apparatus being thus ready, you first introduce through the top of the tower *k, k, k, k*, a few burning coals; and put upon them some of the unkindled fuel of the fire, that the cavity of the tower may, according as it is thought necessary, be filled either entirely or only in part. Then with all speed you put upon it the iron cover, and strew the border of this on the outside with sand, althes, which you press gently with your hands: for if you should neglect this point, all the fuel contained in the tower would be kindled, and may endanger letting the house on fire.

We shall here annex a few general rules concerning the regimen of the fire in this furnace: for it is hardly necessary to explain all particulars, since practice will easily hint them to such as shall be ever so little acquainted with chemistry. The fire may be made very strong in the first chamber *b, b, b, b, i, i*, when the door of the ash-hole *e*, and the funnel *g, g, h, h*, of the chamber is quite open, and when the iron slider, suspended with chains *u, u*, does not hinder the fire from passing freely from the tower into this cavity. But the closer the funnel is shut, together with the door of the ash-hole, the more the violence of the heat diminishes; and this will be soon effected, if the iron slider suspended with chains is let down in part; for the fuel contained in the tower burns at least as high as the space between the lower edge of the iron slider and the grate *d*. Observe besides, in these operations wherein the round hole of the door is stopp'd with a plug, that when the strongest fire is required, this hole must not be kept long open; because the air rushing violently through it, soon cools the bodies put into the cavity. The operations above mentioned may be performed in the second and third chamber, *i, i*, and at the same time, and with the same fire, as they are in the first chamber; for the fire penetrates from the first cavity into the second, and increases when the funnel *z, z, a, a, d, d*, respectively is opened; but before you do this, the funnel of the first cavity must be shut as much as that of the second is opened. By the same means, you may increase the fire, which serves for the operations made in the two first cavities, from going out through the funnels, and you force it out, on the contrary, through the third cavity and through its funnel *s, s, s, s*, that it may also act upon the bodies placed in that cavity. For the more the funnel erected upon the third cavity is open, the more one, or even both funnels of the other two cavities must be closed: thence it is plain, that you cannot kindle the strongest fire in the third cavity, unless there be one equally strong in the other two; and that, on the contrary, the heat in the third cavity may be rendered less, by closing its funnel; though it be violent in the others. The same is true of the second cavity, with regard to the first. Finally, you cannot make the strongest fire under the muffle placed within the upper door *e* of the tower, unless you have an equal fire in the first cavity, which fire may consequently be increased, by shutting the door quite against the muffle *e*, and diminished by opening it; there being mean while an equal heat in the first chamber, and in the following ones. Cramer, and Chem. Dict. Appendix. This sort of furnace is now much neglected, since the long and laborious operations of the ancient chemists, who were in search of the art of making gold, have been discontinued: it is also subject to an inconvenience, as the fuel in the tower is apt to stick there, or fall down at once in too great quantity.

FURNACE, bellows, or blast, is one of the two kinds of furnace used in coinage for the fusion of metals. It consists of a flat hearth at bottom, into which the air may be admitted by a hole contriv'd therein. On a level with the hearth is a second aperture, which gives passage to the pipe of the bellows, from which the furnace is denominat'd: about a foot over this is a moveable grate, which may be taken off, and put on, at pleasure; lastly, over this is the place where the crucible is set, which is square, and made of the same earth with the crucible, of breadth sufficient to bear a range of coals around the crucible. To melt a metal in this furnace, they lay a little plate of forged iron over the grate, and on this they set the crucible, which is likewise covered with an iron or earthen lid; then they fill the furnace with charcoal, and when it is well lighted, and the crucible sufficiently hot, they stop the vent-hole: lastly, throwing on fresh coals, they stop the furnace with an iron lid; thus continuing to work the bellows, and sup-

ply fresh fuel, till the metal be in fusion. These bellows should be double, like those used by the smiths, that the blast may be continual; though no heat can be produced by this means, to exceed that which may be obtained in a good wind-FURNACE. The principal use of bellows is to excite a great heat in a little time.

Dr. Lewis, in his ingenious contrivance of portable FURNACES, proposes to fit up a black leaden crucible or pot with a blast furnace, in which no aperture is required than a round one in the side, through which the nose of the bellows passes; and the fuel is to be thrown in at the top. The pot chosen for this purpose should be of the largest size; and if a cover or dome, or an additional part for enlarging its capacity be wanted, another pot, with a portion of its lower narrow part sawed off, makes a very convenient one. A round plate or slip, sawed from the solid part of the bottom, serves very conveniently both for a grate and for a support to the crucible; eight or nine holes, about three quarters of an inch in diameter, are bored round the outer part of the plate, for the transmission of the air forced in by the bellows, which holes are made to widen downwards, to prevent their being choked up by pieces of the fuel. Four or five small crucibles may be placed together on the middle of this plate. See fig. 79. The bellows which Dr. Lewis chiefly employed is the organ bellows, constructed, that the upper board, instead of rising obliquely on hinges at one side, rises equally on all sides, and continues always horizontal. The leather of this kind of bellows is more flexible than that of the common ones, and does not, like them, refit unequally according to the greater or less extension of the folds. The board is pressed down, and the air forced out by a weight on the top, which weight, acting always perpendicularly, has always an equal power, and the air is driven out in one unvaried current. This advantage may also be given to the common bellows by hanging the weight at the extremity, on an arc, furnished with a groove for receiving the cord, and whose centre is the point on which the board moves: by this contrivance, the heat is kept up uniform, and may be easily increased at pleasure, by increasing the weights; and for this purpose, the nozzle of the bellows should be wider than usual, that the air may be more freely discharged from it. The bellows is of no incumbrance in the LABORATORY, being inclosed in a wooden case, whose cover does the office of a common trolley to the nozzle, which just comes through the cross bar at the bottom of the table, is occasionally fitted a pipe reaching to the furnace. The bellows, thus disposed, will also serve for impelling and concentrating the flame of a lamp on bodies exposed to it. For this purpose, an upright tin tube is fitted on the nozzle by a short elbow at its lower end, and at its upper end is a moveable elbow, into which is inserted a lesser pipe, having a very small aperture in its extremity: this aperture, being applied to the flame of a lamp placed upon the table, and the pipe blown through, the flame lengthens in the direction of the blast, and converges into a small space, producing there a very great heat. The bellows above described may be made lighter and more commodious, by using a stiff rod, for moving the lower board, instead of the flexible cord or chain commonly employed. Some, instead of a bellows, have substituted an Aëolipile, which is about half filled with water, and set on burning charcoal, with its neck directed to and at a small distance from the fire to be excited: as soon as the water begins to boil, an elastic vapour issues vehemently through the small orifice, and animates the fire like air impelled by bellows; whence this instrument has been called the Aëolian bellows and philosophers bellows: some have employed the aëolipile in the same manner as the common bellows, by inserting its neck into the cavity beneath the grate of a furnace; but Dr. Lewis condemns this method, and observes, that, in all cases, where the vapour does not pass through a portion of the atmosphere before its admission to the burning fuel, it extinguishes, instead of exciting, the fire.

In operations which require a considerable degree of continuous heat, it has been proposed to impel a number of flames into one point, by streams of air driven from different parts of the circumference of the fuel to the middle, by means of several bellows placed round the furnace. But a number of bellows being incommensurable, Dr. Lewis has contrived to multiply the streams of air with one bellows. The pot, which serves as a furnace for this purpose, has a number of holes bored at small distances, in spiral lines all over it, from the bottom up to such height as the fuel is designed to reach to. The crucible is placed on a proper support in the bottom, and the holes are obliquely directed towards the crucible, so that the impelled heat plays in a kind of spiral upon its surface: the pot, which serves for the blast

furnace, already described, with an iron ring at the top receives this perforated pot so far, that all its holes are within the cavity, which cavity has no other outlet than the round aperture for the bellows; and, therefore, the air, thus blown in, will distribute itself through the perforations of the inner pot. See fig. 20. C represents the furnace, D a transverse of it, and E is its cover, being an iron plate with a round hole in the middle, and a handle. By means of this contrivance, the crucible is expeditiously heated, and with a small quantity of fuel, to an intense degree; and yet the exterior parts of the fuel have no great heat, so that the operator may approach the apparatus without inconvenience. A close-bottomed pot, like that used for the blast furnace already described, without a grate, will make a furnace for the fusion of metals, the revival of metallic calces, and the fusing or alloying of ores, *trans carbones*, as it is called, or in contact with the burning fuel, as practised in the large works. The furnace being intensely heated, and almost filled with fuel, some of the subject-matter is sprinkled upon the coals, chiefly about the middle, and towards the side opposite to the bellows, but with care that it no where touch the side; more charcoal is thrown over it; and the fire, according to the nature of the subject, is kept up strong, or abated, by lessening the weight upon the bellows; and the alternate injection of the subject-matter and charcoal continued; the metal and slag, melting and dropping down through the coals, are collected from the bottom. Lewis's Com. Phil. Techn. p. 18, &c.

FURNACES for making the four kinds of colours, are those for subliming CINNABAR, for making VERMILION, for subliming KING'S YELLOW, and for calcining blood for making PRUSSIAN BLUE, OXER, ULTRAMARINE, &c. For the method of their construction and use, the curious reader is referred to Dossie's Handmaid to the Arts, vol. i. p. 15, &c.

FURNACE, enamelling. See ENAMEL, and Handmaid to the Arts, vol. i. p. 267, &c.

FURNACE, foundry, is of divers kinds, according to the different kinds of work to be cast. See FOUNDRY of small works, &c.

The statuary, or figure-makers, use two kinds of furnaces; which see described under FOUNDRY of statues.

FURNACE, glass-house, is the place wherein the ingredients or materials of glass are fused and vitrified.

There are three kinds of furnaces used in the glass-works. The first, called the *calcar*, serves to prepare or calcine the fit in. It is made in fashion of an oven, ten feet long, seven broad, and two deep. The fire, which is fuel, is put in a trench, on one side of the furnace; and the flame reverberates from the roof back upon the fit. The coals burn in an iron grate, and the ashes fall hence into a hole underneath.

The second is the *working furnace*, serving to melt the metal in, or make the glass. Its figure is round, three yards in diameter, and two high, being arched over: round the inside there are eight or more pots placed, and piling-pots on these: the number of pots is always double that of the boccas or mouths, or that of the workmen, that each may have one pot refined to work out of, and another for metal to refine in, while he works out the former.

The furnace has two partitions: the lower separating the pots from the fire-place, has a circular hole in the centre, covered with a grate, through which the flame passes from the fire-place into the furnace; from the arched sides and roof whereof it is reverberated into the melting-pots.

The second partition divides this from the *leer*, or annealing furnace: through the boccas, or working-holes, the metal is taken out of the pots, and the pots put into the furnace: these boccas are stopped with moveable covers, made of lute and brick, to screen the workmen's eyes from the fire: on each side the boca is a bocarella, out of which coloured glass, or the finer metal, is taken from the piling-pot. To the furnace, likewise, belong ovens, or holes, near the leer, for the calcining of tartar, iron, &c.

The *leer*, which serves to anneal and cool the vessels, and which Agricola makes a particular furnace, consists of a tower, besides the leer: the tower lies directly over the melting furnace, with a partition betwixt them a foot thick, having an aperture, called *achis*, or *lumelle*, through which the flame or heat ascends out of the furnace into the tower: on the floor or bottom of this tower, the vessels, fashioned by the artists, are set to anneal; this has also two boccas, or mouths, by which the glasses are put in with a fork, and set on the floor.

The leer is an avenue five or six yards long, continued to the tower; through this the glasses, when annealed, are drawn in iron pans, called *fraches*, by which they come

* to cool by degrees; being quite cold, by that time they reach the mouth of the leer, which enters the farol, or room where the glasses are to be let.

The third is the *grain-glass furnace*, which is a kind of compound of all the former. It is made square (the two former being circular), having an arch at each angle thereof for annealing and cooling the glasses. The metal is wrought on the two opposite sides, and on the other two they have their calcars, into which are made lunettes for the fire to come from the furnace, to bake the frit; as, also, to discharge the smok. Fires are made in the arches, to anneal the vessels; so that the whole process is done in one furnace.

The materials whereof the infides of these furnaces are built, are not brick (which would soon melt down into glass, as also all the softer stones), but hard and sandy kinds, by Imperatus called *pyramalia*. See GLASS, and GLASS-POTS.

FURNACE, glass painter. See PAINTING, in GLASS.

FURNACE, hatters, are of three kinds; a little one under the mould whereon they form their hats; a larger, in the scowering room, under a little copper fall of water and leas; and a very large one under the great copper, in which they dye their watts.

FURNACE, lamp, is a kind of *athanor*, in which the heat is produced and maintained by the flame of a lamp introduced within it. This furnace has evidently no occasion for an all-hole, a grate, or a fire place. It has only one opening below, through which the lamp is introduced, and a kind of small chimney made in its upper and lateral part, for circulation of air, to keep up the flame of the lamp, and to give vent to the smoke. A furnace of this kind is very convenient for distillations, which require little heat. It may be easily furnished with a water-bath, or sand-bath; and it is particularly useful for digestions. Dr. Lewis observes, that in the common lamp-furnaces, the lamps require frequent snuffing, and smoke much; and the foot, accumulated on the bottom of the vessel placed over them, is apt, at times, to fall down, and put out the flame. These inconveniences were, in a great measure, remedied by the following construction.

The lamp consists of a brass pipe, ten or twelve inches long, and about a quarter of an inch wide, inserted at one end into the reservoir of the oil, and turned up at the other to an elbow, like the hole of a tobacco-pipe, the aperture of which is extended to the width of near two inches. On this aperture is fitted a round plate, having five, six, or seven small holes, at equal distances, round its outer part, into which are inserted as many pipes about an inch long; into these pipes are drawn threads of cotton, all together not exceeding what in the common lamps form one wick; by this division of the wick, the flame exposes a larger surface to the action of the air, the fuliginous matter is consumed and carried off, and the lamp burns clear and vivid.

The reservoir is a cylindric vessel, eight or ten inches wide, composed of three parts, with a cover on the top. The middle partition communicates, by the lateral pipe, with the wicks; and has an upright open pipe soldered into its bottom, whose top reaches as high as the level of the wicks, so that, when this part is charged with oil, till the oil rises up to the wicks in the other end of the lamp, any farther addition of oil will run down through the upright pipe into the lower division of the reservoir. The upper division is designed for supplying oil to the middle one; and, for that purpose, is furnished with a cock in the bottom, which is turned more or less, by a key on the outside, that the oil may drop fast enough to supply the consumption, or rather faster, for the overplus is of no inconvenience, being carried off by the upright pipe; so that the oil is always, by this means, kept exactly at the same height in the lamp. For common uses, the middle division alone may be made to suffice: for, on account of its width, the sinking of the oil will not be considerable in several hours burning. In either case, however, it is expedient to renew the wicks every two or three days: oftener or seldom, according as the oil is more or less foul; for its impure matter, gradually left in the wicks, occasions the flame to become more and more dull. For the more convenient renewing of them, there should be two of the perforated plates; that, when one is removed, another with wicks, fitted to it, may be ready to supply its place.

One of the black-lead pots, described under the article *portable* FURNACES, makes a proper furnace for the lamp. A pot of this kind requires no other aperture than one in the bottom for admitting air, and one in the side for the introduction of the elbow of the lamp. The stopper of the side aperture consists of two pieces, that it may be conveniently put in after the lamp is introduced; and it has a round hole at its bottom fitting the pipe of the

lamp. By these means, the furnace being set on a trivet or open foot, the air enters only underneath, and spreads equally all round, without coming in streams; whence the flame burns steady. The heat should not be raised higher than about the 450th degree of Fahrenheit's thermometer, which degree of heat is somewhat more than sufficient for keeping tin in perfect fusion. See fig. 47. Over the lamp furnace, as represented in the figure, there is a broad pan, which is employed as a water-bath, and contains a long-necked matrass or salt-head, whose commodious vessel of the same kind, surrounded by a glass receiver, with a long pipe inserted into its mouth, and a cucurbit, or body with a glass-head, for distillation, Lewis's Com. Phil. Techn. p. 29.

FURNACE, letter-founders, is very small, not exceeding a foot and a half in height, and a foot in diameter; being placed on a wooden stand, or bench, to raise it to a proper height for the artist, who works standing. It is made of the same earth with crucibles. See LETTER-FOUNDRERY.

FURNACE, lathe for. See LATHE.

FURNACE, melting. See MIND FURNACE.

FURNACE, plumbers, is of three kinds: in the first they melt the lead, whereof there is to be call.

This is only a sort of large copper, or receptacle like a copper, made of free-stone, and coated well round with potter's clay, having a little iron pan at bottom.

In the second they melt the lead to be cast in moulds for pipes, &c. which are not to be soldered.

The third is the tinning furnace, which is a square frame of wood, or sometimes a mass of stone-work with a brick hearth, whereon is made a charcoal fire, which serves them for the applying of thin tin leaves on the works. See PLUMBERY.

FURNACES for baking and burning porcelain, or China ware. See PORCELAIN.

FURNACES, portable, are those, which, with regard to their size, and the facility and moderate charge of their construction, are peculiarly adapted to experimental enquiries. The term *portable*, when applied to furnaces, more generally, and in opposition to *fixed*, has been actually explained. Under this head we shall present account of Dr. Lewis's ingenious contrivance in the construction of such furnaces. For this purpose he made use of black lead crucibles, of the size marked up, the dimensions of which are about twelve inches high, the hollow near eight inches wide at the mouth, and about the middle of their height six and a half. Each crucible has its mouth ground smooth and flat, upon a stone, with a little sand; and a round hole sawed in its bottom with the common compass saw of the carpenter. In the side, a little above the bottom, another round hole is made, and opposite to this a square one; above which is cut a larger square one. See fig. 42. A. All the apertures are fitted with stoppers, cut out of pieces of brown crucibles; the square apertures are made little narrower internally than externally, at each of their sides, so that the stoppers, whose outward surface is even with that of the outside of the pot, can neither be pushed inward, nor fall out, when the pot stands on either end. The round stoppers are made to fit close, by grinding them into the apertures; and they are taken out with a kind of fork, the points of which are introduced into two small holes in each stopper, and at the same distance from one another in all of them. The grate for this furnace consists of an iron ring, with cross bars fixed in it. See fig. 42. B. Three of these grates of different widths, are required for different uses: one of which is made to rest against the converging sides of the pot, in the lower narrow part, just above the lowermost square hole; another so large that it may enter no farther than nearly to the top of the uppermost hole; and the third of the same width with the outside of the mouth of the crucible. The lower and middle grates are supported either by grooves round the pot, or by pins in their circumference, resting on notches within the pot. A grate might be made for these furnaces of four or five iron rings, placed within one another, each of which should be furnished with three pins at equal distances, projecting from its circumference; and the pins of the inner ring should be contrived to drop down into corresponding notches made in the next, and the pins of the second rings into notches in the third; the notches being made in the middle of the spaces between every two pins. A grate of this kind, being composed of moveable parts, may be enlarged or diminished at pleasure, so as to fit furnaces of different widths, by adding or removing a ring on the outside.

In order to render the furnaces sufficiently durable, they are bound round in three or four different parts, with copper-wire, about the fix of a crow quill, and made pliable by heating it on live coals, so as not to interfere with the doors or holes; or they may be surrounded by iron

iron or copper hoops, instead of wire. In either case the mouth is effectually secured by a thin copper hoop, which prevents the edges from breaking or wearing; and the small space left between the furnace and the upper edge of the hoop is filled with a lime moist loam, or with clay mixed with powdered pots. The inside of the furnace should be washed over with Stourbridge clay, diluted in water; and when it is designed for continued fronging, or for bearing the action of corrosive bodies, it should be lined to some thickness with a lute, composed of Stourbridge clay, beaten up with about twice its measure of coarse sand, or of glass-house pots, in coarse powder. The handle of these furnaces is made of an iron rod, or strong iron wire, about three feet long, bent like the hals of a pall to the width of the furnace, and fastened in two opposite holes made in the furnace through the copper hoop.

Besides the black-lead crucibles, which make the body of the furnace, there are required a foot for them to stand upon, a chimney, and an iron hoop. The best sort of foot is a flat, heavy, iron ring, with three legs five or six inches high, in one of which is a screw for raising or lowering it, so that the furnace may be made to stand level on an uneven floor. A foot may also be formed of an inverted crucible, by making an aperture in the bottom, and fawing three arches at equal distances in the sides, so as to leave between them legs of sufficient strength; or an inverted furnace will answer the purpose. The ashes that fall down are received in an iron pan, placed underneath.

The chimney is composed of three pipes of forged iron plate, not less than one eighth of an inch thick; and each of the pipes is a foot and a half, or two feet long. The lowest pipe is encased with a heavy ring about an inch above the lower end, which enters into the hole in the top of the inverted pot, in order to keep it steady; the upper end of the second pipe is received into the lower end of the next, and the end of this is in the same manner received by the third. The upper end of the chimney is made square, that it may fit into the larger door of the furnace, and serve occasionally as a lateral chimney.

The hoop is formed of a forged iron plate, not less than one sixth of an inch thick, turned round and welded to each end of the ends. See a perpendicular section of it, fig. 42. C. It is about six inches deep, and of the same width externally with the top of the furnace, but its thickness being less than that of the furnace, it is internally wider. One end of this hollow cylinder has an iron ring passing round it within side, and on this end it commonly stands upon the mouth of one of the pots: near this end is a semicircular aperture, whole door is rivetted on a large iron plate, which opens downwards on hinges, and drops no lower than to a horizontal situation. See fig. 42. D.

One of the black lead crucibles prepared in the manner above described, with the lower small grate introduced into it, is a furnace for open fire; the lower square aperture under the grate is the door of the ash-pit, and the upper one above the grate is a door to the fire-place. The fuel, which is always charcoal, is put in at the top, and is supplied with air through the apertures beneath the grate; by closing or opening which, the fire is diminished or increased.

By introducing into the open furnace an iron pot, empty, or containing sand, this becomes a furnace for a capsule, crucible, or sand furnace, in which case the fuel is put in through the fire-place door.

Farther, a vessel broader than the furnace may be placed on the top, with three iron supporters under it, to procure a space for the passage of the air. The flat iron pan used on other occasions for receiving the ashes, may be employed in this manner as a vessel for calcinations, for the evaporation of solutions of lixivial salts, &c. For vessels of a deeper kind, as a copper still, the capacity of the furnace is increased by placing over it the iron hoop, by which it is enabled to receive the body of a still, of a size sufficient for the purposes of an experimental laboratory. See STILL.

If one pot be inverted over the other, with the iron hoop between them, we shall have a furnace for capellation, calcination under a muffle, and the other purposes of that which is called the *small furnace*; and also for experiments of enamelling, of baking colours on earthenware and glass, &c. The chimney, or a part of it, may be occasionally set upon the top, for raising the fire when it proves too languid. The same combination of the two pots and hoop will serve as a *reverberatory*, for distillation in coated glass retorts, earthen retorts, or long-necks, provided that the middle grate be introduced into the undermost pot, and two iron bars be laid across in its upper part, to support the distilling vessel, whilst its

neck comes out at the door of the hoop. The *reverberatory* and *ash-pit* furnaces are, in reality no other than the *small furnace*, with a muffle or a retort in the fire instead of a crucible.

Furnaces of this kind may be used as a common stove, for keeping a room warm with a small quantity of fuel. For this purpose the small grate is introduced into the lower part of the undermost pot, the fire-place door is closed, and the ash-pit door, or bottom hole left open for admitting air. It is then charged with small pieces of charcoal with lighted coals thrown above them, its top is covered by the largest of the grates, on which is placed the hoop and dome, filled with balls of baked earth, or with pieces of brick, so disposed as to leave small vacuities between them. When the stove is placed in the middle of a room, its injurious air may be carried off by a pipe inserted laterally into the larger door of the dome, and communicating at the other end, which should be raised eight or ten inches, with the chimney of the room; and all other apertures of the dome should be closed. The furnace, thus charged, will keep up a moderate, and nearly equal warmth for many hours, without injury or offence. See fig. 43. See *Belmont FURNACE* and *Wind FURNACE*. See also *LABORATORY*.

FURNACE, reverberatory, or reverberatory, is a simple furnace, the fire-place of which is covered with a piece of the same diameter and form as the furnace, which is generally cylindrical. This piece is crossed in its lower part by two bars of iron placed horizontally and parallel to each other, and at its upper edge it has a semi-circular cut. This piece forms a third cavity, which is called the laboratory, because it is intended to receive the retorts, containing the matter to be distilled. The semi-circular cut is made to give passage to the neck of the retort, which ought to be inclined at an angle of forty five degrees. The two bars at the bottom of the laboratory are designed to support the vessel placed there. Above the piece last described, there is placed a fourth piece, in the form of a spherical cap, or an inverted dome, of equal diameter with that of the other piece to which it is fitted; in its lower edge there is a semicircular cut, corresponding with that of the lower piece; and these together form a circular opening; the dome has in its top another opening, or short tube, through which the air contained in the furnace passes, and serving for a kind of chimney. The use of the dome is to keep the heat all round the retort, and to apply a certain degree of heat to the upper part or vault of the retort, by reflecting or reverberating it; whence it is called a *reverberatory*. In consequence of this disposition, the vapours which rise in the retort are determined more efficaciously to pass through its neck. Reverberatory furnaces are used for distillations with a retort, in which a certain degree of heat is necessary, and distillation may be performed in them either in naked fire, by placing the retort immediately on the bars, or in a sand bath, by placing on these bars an iron vessel, with a semi-circular cut in its upper edge, containing fine sand to the thickness of one or two fingers; then the retort is placed in the vessel, and it is so fitted with sand up to the arch of the retort: See fig. 44, in which we represent the ash-hole door; the fire-place door; *a, a, a*, the registers; *b*, the dome or reverberatory; *c*, the conical funnel; *d*, the retort in the furnace; *e*, the receivers; and *f, f*, the iron bars for sustaining the retort.

FURNACE, simple, is a kind of bellows-tower, cylindrical or prismatic, with two doors, or principal openings, the one below, called the door of the ash-hole, and the other immediately above this, called the door of the fire-place. Between these two doors a grate is placed horizontally across the interior part of the furnace, dividing its whole cavity into two parts, the lower part being called the ash-hole, because it receives the ashes which fall from the fire-place. The door of the ash-hole gives admittance to the air for maintaining the fire within the furnace. The upper cavity is called the fire-place, because it contains the combustible matters; and fresh fuel is introduced through the door of the fire-place.

This furnace is sufficient for many chemical operations: in the first place, amidst the coals, crucibles may be placed for the fusion of fusible materials, as lead, tin, bismuth, &c. or for the calcination of matters which require but little heat for their calcination, such as the alkali for making Prussian blue, bezor mineral, &c. On this furnace may also be placed basins for evaporation, alembics for distilling in the water-bath, pots filled with sand for digestions and distillations to be performed by means of a sand bath and a gentle heat, either with alembics or retorts. For operations requiring a longer duration, this furnace is formed into an *ATHANOR*. See *FURNACE*, called *ATHANOR*. Macquer's Chem. Dict. Eng. edit.

FURNACES, *smelting*. See ORES and SMELTING.

FURNACE, wind, is the second furnace used in the fusion of metals for coinage. At bottom it has a hearth made hollow, in manner of a cupel, with a vent-hole in the fore-part thereof; over the vent-hole is a grate fixed in the malle of the furnace; over the grate is the place for the crucible, which is usually of forged iron.

The fire being lighted, the crucible is set in, with a cover over it, and a capital, or cover of earth or iron, is laid likewise over the furnace; and at the top of this capital is a hole, five or six inches in diameter.

It is called *wind-furnace*, because the air, entering through the vent-hole at bottom, which is always open, serves the same purpose as the bellows in other furnaces.

Gold is usually melted in the bellows-furnace, as requiring an intenser heat before it fuses. Silver and copper are commonly melted by the *wind-furnace*.

Cramer, in his *Art of Assaying Metals*, gives the following account of the construction and uses of the *wind or melting-furnace*: It is formed of iron plates, the interior surfaces of which are covered with lute. The cavity of it may be formed according to an elliptical mould.

1. Make an hollow ellipsis, the foci twelve inches asunder, and the ordinate five inches long, cut it off in both its foci, that it may assume the figure *fig. 45*. 2. Then make in this hollow body, and near its lower aperture, four holes, eight lines in diameter, and directly opposite *c, c*. 3. Then fasten two flat iron rings *d*, almost one inch and a half broad, at both the upper and the lower inward edge of this oval cavity; and fill the inside of it with small iron hooks, joining out about six lines, and three or four inches distant from each other. These, together with the rings just mentioned, serve to fasten the lute. Thus will the body of the furnace be made: only you must add at the outside two iron handles *e, e*, to be riveted on each side of it, that it may be taken hold of and moved. 4. Then make the cover of the furnace, which may be formed like the part cut off from the ellipsis *fig. 46*. Let this have an opening *b* made in it, four inches high, five inches broad at bottom, and four inches at the top; and adapt to this an iron door hung on hinges to shut it close, and having at the inside a border fastened to it, answering exactly to the circumference of the door, and as prominent inwardly as the thickness of the lute to be applied to it requires: for the same purpose, let small iron hooks be fastened to the inside of the door, which is intercepted by the said border. And lest this cover should be burnt within by the force of the fire, you must cover the inside of it with the LUTE described under that article: therefore it must be likewise furnished with a ring and iron hooks to fasten the lute: as was said before, when we spoke of the body of this furnace.

Besides this, you must fasten two iron handles *fig. 46*, *g, g*, on the outside of this cover. Then a round hole must be made in the top *h, h*, being three inches in diameter, prolonged into a hollow tube *d* almost cylindrical, and a few inches high, upon which the iron funnel described may, in case of necessity, be put after the manner mentioned in the same place where we spoke of the assay-oven. 5. After this the lining of both the body and cover of the furnace within is made in the same manner above described. Moreover, you must make for this furnace two moveable bottoms; viz. one to receive the ashes, and admit the air; the other to serve for reductions. The first is made with an iron plate, formed into a hollow cylinder, open at top, and to be shut at bottom with an orbicular iron plate, as with a baffle, five inches high, and of such a diameter, as that it may receive the interior orifice of the body of the furnace, *fig. 45*, the depth of half an inch. See *fig. 47*, therefore let an iron ring *e*, half an inch broad, be fastened on the inside of the said bottom, and at the distance of half an inch from its upper border, to support the body of the furnace put into it. Again, let this bottom have a square door, four inches high, and as many inches broad, that may be shut closely, with a door hung on hinges, that you may, by means of it, diminish or increase the draught of the air, and thus govern the fire at pleasure. Then, on the left side of the door, and at about half the height of this bottom part, let a round hole *a* be made, one inch and a half in diameter, to admit the pipe of the bellows when need requires. Next to this, let another bottom part be made of the same matter and figure as the foregoing: let it likewise be of the same diameter, but two inches higher, so that it may be of the height of seven inches. Likewise let it have round it a like iron ring below its upper border, to support the body of the furnace to be received in it. But let a hole two or three inches broad, and one inch high, *fig. 48*, *a*, be cut out just below the ring, in the side of this bottom part; then let another round hole be made in the left side of this

first hole, fit to admit the pipe of the bellows *d*. Farther, let another round hole like the foregoing *e* be made on the right, and at the distance of one inch from the bottom: then let the whole inside of this bottom part (the part above the ring excepted) be overlaid with lute, and a bed be made at the bottom, of a figure like that represented by the line *fig. 48*, *b*. The matter of which this is made is common lute pulverised, passed through a sieve, and mixed with such a quantity of dust of charcoal fine as in the same manner, so that the mixture being rammed and pressed down, may at least be lightly coherent. Of this matter pressed on the bottom of the bottom part, a bed is made like the segment of a sphere, having in the middle a small cavity somewhat lower, and made extremely smooth, after the manner proper for large still vessels or cells.

This furnace is chiefly fit for fusions, which may be made in it with and without vessels. When you are to melt with a vessel, put the body of the furnace, *fig. 45*, upon the first bottom, *fig. 47*, that has a door to it to open and shut; introduce two iron bars through the holes of the furnace, *fig. 45*, *c, c*, put upon them the iron grate, which you are to introduce through the upper mouth of the furnace: then put in the middle of this grate a brick or square tile, very smooth every where, warmed, and perfectly dry: otherwise, the vessels put upon it, especially the large ones, are easily split by the moist vapours coming out of it in the operations. Let the height and width of this stone be a small matter broader and higher than the bottom of the crucible or pot to be set upon it; for if it were less high, the bottom of the vessel could not be sufficiently warmed; and if it were less broad, the vessel might easily fall from it: then put upon this tile the vessel containing the matter to be melted, and surround it immediately with coals on every side, which must be ranged according to the method prescribed before, in our description of the *assay-furnace*: then you govern the fire, by opening and shutting the door of the ash-hole, *fig. 47*, *b*: you excite it by putting the cover, *fig. 46*, upon the body of the furnace; and if, besides, you put a funnel upon the cylindrical mouth *a* of this cover, the melting fire becomes still more violent: but if you moreover introduce the bellows through the hole of the bottom part, *fig. 47*, *d*, and the joint of the furnace with the bottom part, and the door of the bottom part, unless it can be shut very close, being exactly done with thin lute, or Windor loam, the fire thus excited by the blast of the bellows is carried to the highest degree, and far surpasses that which may be made in a smith's forge. Another advantage of this method is, that the vessels are not so easily broken, because the blowing of the bellows cannot affect them immediately, and because a fire perfectly equal is excited on every side. One may easily examine with this apparatus, how bones are affected by the violence of the fire only. Now, if you have a mind to perform any operation without a vessel, and with a naked fire; for instance, to melt and reduce the calces or scorification of copper, tin, lead, and iron, or the ores of these metals; the body of the furnace must be put upon the other pedestal, having a bed in it, *fig. 48*. However, you must, before this, open with a knife the oblong hole *a*, and the round one *d* of this bottom part, which are stopped with the lute sticking to the inside: then you apply at the round hole *a* on the left side the bellows, in such manner that the nozzle of it, being directed obliquely downwards, may blow strongly against the bed *fig. 48*, *b*: by this means, all the ashes that fall into the bed are blown away, and the strength of the fire determined to a degree, that all the melted bodies that fall into the said bed remain in their state of fusion; and were it otherwise, the melted bodies would immediately wax cold, and adhere in grains to the bed, whereas they ought to have melted into one regulus. The oblong hole in the fore-part of this bottom part *a*, serves to discover, by means of a poker, whether the matter in the bed be melted or not: it serves likewise to take away through it whatever might stop the bellows, and, in some cases, to take away the scorification: then you put fresh coals into the furnace one span high, and blow them well with the bellows, to make them burn, that the bed may be very hot before the matter to be melted is put into it: for if this is not previously done, the melted mass seldom runs into a regulus, but remains dispersed among the scorification, which soon grow hard. The bed being well heated, and fresh coals added to the fire, put into it such a quantity of the matter to be melted as cannot hinder the fire from being carried to the requisite degree; which cannot be determined otherwise than by experience: again, put fresh coals, and upon them another quantity of the matter to be melted; they may be, like straw, one upon another: but if the mass, once melted, could not long sustain the strength of the fire, or if you had a mind to melt a greater quantity

quantity of matter than what can be contained in the bed, you must open the round lower hole, *fig. 48. c.* that you may make a channel passing from that hole through the lute, and reaching to the small cavity at the bottom of the bed *g.* to this hole, at the outside, apply an earthen dish like the bed within, or any proper recipient, surrounded with burning coals, into which the matter melted running from the bed through the hole, *fig. 48. c.* may be collected, as represented by *fig. 49.*

With regard to the elliptic or parabolic figure of the fire and dome of a furnace, we may observe, that many have recommended this form of construction, expecting that the rays of fire, striking all over the internal surface, would be reflected back into a small focal space, in the same manner as the solar rays are concentrated by burning concave specula. An elliptic furnace was procured with great care by Dr. Lewis; but he was much disappointed in its effects; for he could not find, that any focal reflection obtained in it, or that any advantage resulted from the exactness of its figure, or from the precise species of its curvature. *Com. Phil. Techn. p. 26.*

The melting furnace used in the manufacture of brass is in the form of the frustum of a hollow cone. At the bottom of the furnace, or greater basis of the frustum, is a circular grate, or iron plate, which is covered with a coat of clay and horse-dung, to defend it from the action of the fire, and pierced with holes, through which the air, maintaining the fire, passes. The crucibles, filled with the proper materials (see BRASS), stand upon the circular plate, forming a circular row with one in the middle. The fuel is placed between the crucibles, and is thrown into the furnace at the upper part of it, or the lesser basis of the frustum, in which is fitted a cover made of bricks or clay, kept together by bars of iron, and pierced with holes. This cover serves as a register; when the heat is to be increased, the cover is partly or entirely taken off, and a free draught is permitted to the external air, which passes along a vault under-ground to the air-hole, through the holes in the circular grate or plate, between the crucibles, and through the upper mouth, along with the smoke and flame, into an area, where the workmen stand, which is covered with a large dome of chimney, through which the smoke and air escape. When the heat is to be diminished, the mouth of the furnace is closed with the lid, through the holes of which the air, smoke, and flame pass. The crucibles are to be kept red-hot during eight or ten hours, and in some places much longer, even for several days, according to the quality of the calamine, during which time the zinc rises in vapour from the calamine, unites with the copper, and renders that metal fusible by considerably less heat than it is alone. To render the metal very fluid, that it may flow into one uniform mass at the bottom, the fire is to be increased a little before the crucibles are taken out, for pouring the fluid metal into moulds. By this process, forty pounds of brass may be obtained from fifty pounds of good calamine, and forty pounds of copper, though a considerable quantity of zinc is burnt and dissipated during the operation; but less of this vapour escapes by using granulated copper. See GRANULATION. Macquer's Chem. Dict. Eng. ed. note, under BRASS.

Dr. Lewis, in his apparatus of portable furnaces, constructs a wind furnace, for the fusion of metals, the assaying of ores, and similar operations, by inverting one pot over the other, and placing on the top either the entire chimney, described under portable FURNACES, or two, or one of its pipes, according to the degree of fire which is required. The second fixed grate is preferable to the smaller one, because it has more interstices for admitting air to the fuel. The crucible, containing the materials for operation, is placed on a circular slip of brick, or of a broken pot, a little wider than its bottom, laid on the middle of the grate, to prevent the impact of the cold air. The charcoal is put in through the fire-place door, or larger aperture of the dome, or upper pot, which should always be closed after each supply of fuel. The furnace stands on its trier, or open foot, with the flat iron pan underneath, which serves to receive the ashes, and to preserve the fluid contents of the crucible, if it should happen to fall, during the fusion. The two opposite holes in the upper part of the dome afford the convenience of passing an iron rod through, for safely lifting it when intensely heated. See *fig. 50.* This furnace may be easily converted into a blast furnace, by introducing the nose of a pair of double bellows into the round hole in its side; in which case, all the other apertures beneath the grate must be closed, while the bellows acts, that the air forced in by it may be prevented from escaping. A stronger wind furnace, capable of bearing a long continuance of vehement fire, may be constructed of two

large pots; the lowermost of which has only a round hole in the bottom for admitting air; and the upper one, or dome, a similar hole, corresponding to the chimney, with a door in the side, through which the fuel is put in. The furnace is placed upon an inverted pot, which has a hole in its top answering to that in the bottom of the furnace, another large one in its side, and its mouth ground smooth, that it may apply itself every where close upon the flat stone, or iron plate, which serves as a stand for it. Into the side aperture of this lower pot, which is both the foot and air-pit of the furnace, an iron pipe is inserted, somewhat wider than the widest part of the chimney, and two or three feet long, on the end of which may be fitted a wooden one of more considerable length.

The whole of this pipe may be laid horizontal, to at to reach into an adjoining apartment; or rather, if there is a convenience, the wooden pipe may be sunk perpendicularly through the floor into a room underneath, and the horizontal iron one joined laterally to it at the top; its use is for conveying into the furnace, instead of the adjacent air rarified by the heat, the colder and denser air at a distance; and its effect in animating the fire will be in proportion to the coldness and denseness of the air to which it reaches.

This furnace is represented in *fig. 51.* The pipe of a bellows may be adapted to a hole made in the side of the foot, or air-pit, of this furnace, for producing a more vehement fire; and the air-pipe is at the same time stopped by means of a moveable register in the end near the furnace. This register is a circular iron plate, fixed on an axis, which is placed across the pipe; the extremity of the axis projecting on the outside, the plate is thereby readily turned, so as either to allow a free passage for the air, or to close the whole bore of the pipe. *Lewis's Com. Phil. Techn. p. 21. 28. &c.*

FURNACE of a mine, in the *Art of War.* See CHAMBER and MINE.

FURNACE. See FURNACE.

FURNITURE, in Dialling, certain additional points and lines drawn on a dial, by way of ornament.

Such are the signs of the zodiac, length of days, parallels of declination, azimuths, meridians of the principal cities, Babylonian and Italian hours, points of the compass, &c. See DIAL.

For drawing furniture on dials, the ANALEMMA, or trigon of figures, is an instrument of principal use.

FURO, in Zoology, a name given by some authors to the VERMILION, called by others also *vermiculus* and *stilis*.

FUROR uterinus, a species of madness, peculiar to women, existing them to a vehement desire of venery, and rendering them insatiable therein, and manifesting itself by obscene speech and wanton behaviour. As the disorder increases, the patient scolds, laughs, and cries by turns. The immediate causes of this disease are an inflammation, tenderness, and irritability of the uterus and passages of women, and particularly of the clitoris and vagina, in which the several humours collect, or the too great abundance and acrimony of the humours of these parts. In order to the cure, which, if the disorder be taken in time, may be expected, the patient should be bled in proportion to her strength. Camphor, in doses of fifteen or twenty grains, with nitre, and small doses of the Thebaic nodule, may be repeated at proper intervals. Some prescribe the saccharum in doses of three to five grains. Besides bleeding, cooling purges should also be repeated in proportion to the violence of the symptoms, &c. What is useful in maniac and hypochondriac disorders, is also proper in this case, regard being had to the constitution and habit of the patient. Injections of barley water, with a small quantity of hemlock juice, may be frequently thrown up into the uterus, and these have been much recommended.

FURR, or FUR, in Commerce, the skins of divers kinds of wild beasts, dressed with the hair on to be used as a lining, or doubling, of garments, robes, &c. either for warmth, ornament, or distinction of rank and dignity. The word is formed of the French *fourrer*, a lining; which Du-Cange derives from *furere*, also, in the barbarous Latin, for the same thing. We also meet with *foraturus*, *fuleratus*, *fulcratus*, and *fulcratus*, in the same sense.

The robes of kings, dukes, and peers, are lined with divers kinds of *furri*, and, in particular, ermine, to render them more magnificent.

The same may be observed of several chief magistrates, judges, and doctors of different faculties, in the universities.

The kinds of *furres*, or skins, chiefly dressed in a lining, and with the hair on, are those of the ermine, sable, squirrel, coney, cat, otter, dog, fox, wolf, tiger, bear, &c. The statue 28 Hen. VIII. cap. 12. mentions divers kinds of *furri*, viz. *sabli*, which are a rich *fur*, of colour be

tween black and brown, the skin of a beast called a *fable*, in bigness between a pole-cat and an ordinary cat, bred in Russia and Tartary; *laurus*, the skin of a beast of that name, nearly the size of a mout, in colour neither red nor brown, but between both, mingled with black spots; they are bred in Blucovy, and their skins are a very rich *furs*; *gambis*, a beast's skin so called, in size between a cat and a weasel, marked like a cat, and of that nature; they are of two kinds, black and grey; of the black is most precious, which hath black spots upon it, hardly to be seen; this is the product of Spain; *zibex*, which are of fuligin like the fable, the top of the *furs* black, and the ground whitish, bred for the most part in France; the *muskrat*, a beast very like the fable, the skin resembling coarser, produced in England and Ireland, and all countries not too cold; but the best are from Iceland. Besides these, there are the *fish* and *pelican*; the *salicet*, a little beast in size near the squirrel; *miniver*, being the bodies of squirrels; and *skunk*, or what is called *badger*, &c. all of them *furs* of foreign countries; some whereof make a large branch of their inland traffic.

FURS, *timber*, &c. See **Timber**.

FURS, in *Medicine*, a representation of the skins of certain wild beasts, seen, both in the doublings of the mantles of coat-armour, and in the smooch stick.

The heralds use two metals, five colours, and two *furs*, or hairy things; viz. ermine and vair.

The origin of these *furs* Mackenry ascribes to the fields being anciently covered with skins, which skins, or coverings, were afterwards represented in the shields; a more probable derivation, in our opinion, than to say they were placed on shields, because they had been worn in mantles and garments.

Furs either consist of one colour, which is white; or more than one; and these either one, or more than two.

Furs of two colours are either ermine, being white with black spots; erminois, black with white spots; erminois, whose ground is yellow; and the powdering black; or pean, which is black powdered with yellow.

Furs of more than two colours are called *VAIR*, and *VAIRY*.

FURRIER, a person who trades, or works, in *furs*, or furs robes, &c. *threswith*.

FURRING of a ship, is laying on double planks on her sides.

This is done after the ship is built, and is by the sailors called *plank upon plank*; but there is another way of *furring*, which is more properly so called; and that is, when a ship's planks are ripped, and new timbers are put on the former timbers, and on them other planks; which is done sometimes to make a ship bear the seas better.

FURRINGS, or **POKERS**, in *Architecture*, the making good of the rafters-fer in the cornice.

When rafters are cut with a knee, these *furrings* are pieces which go fast along with the rafters, from the top of the knee to the cornice.

When rafters are rotten, or sunk hollow in the middle, there are pieces cut thick in the middle, and tapering towards each end, which are nailed upon them to make them straight. Such pieces are called *furs*; and the putting them on is called *furring* the rafters.

FURROW, among *Gardeners*, denotes a ridge or swelling on the side of a rice, field, or fruit.

FURROW is also used for the deep trench left between ridges, to drain off the superfluous moisture.

FURUNCULUS, in *Surgery*. See **BOIL**.

FURUNCULUS, in *Zoology*, the name given by many authors to the *PARVITY* called also the *fox* and *stiff*.

FURZE, **GOSW**, or **WHIN**, *Ulex*, in *Botany*, a genus of the *didymophylla* class. Its characters are these: the flower has a two-leaved calyx, and is of the butterfly kind, and has five petals; the standard is large, erect, oval, heart-shaped, and indented at the point; the wings are flatter and oblong; the keel is composed of two obtuse petals, whose borders are joined at the bottom. It has ten stamens, nine joined, and one separate, terminated by single filaments; with an oblong cylindrical germen supporting a single style, crowned by a small obtuse stigma; the germen afterwards turns to an oblong turged pod, with one cell, opening with two valves, inclosing a row of kidney shaped seeds. There are two species, the common one of which is too well known to need description.

These plants propagate themselves very plentifully by seeds; for as the seeds ripen, the pods open with the warmth of the sun, and the seeds are cast out by an elastic spring to a great distance all around; where they soon vegetate, and are not easily destroyed when well rooted.

Some years ago the seeds of this plant were sown to form hedges about fields; where, if the soil was light, the plants soon became strong enough for a defence against cattle; but as the hedges in a few years became naked at the bottom, and some of the plants frequently failed,

which made gaps in the fence, this method has of late been diffused. But some persons who have sown the seeds of this plant upon very poor, hungry, gravelly, or sandy land, have reaped more profit than they could make of the ground by another crop, especially in places where fuel is dear; where this *furze* is frequently used for heating ovens, drying malt, and burning lime and bricks.

The tops of *furze* bruised, in order to cut the skin sharp points, have lately been found to be excellent to dress cattle, particularly for hives. Those that have been less and sickly have often recovered, and planted upon a short time by the use of this fodder. When *furze* is raised for this purpose, the seeds should be sown in February, March, or April, on ground previously prepared, as for barley, and afterwards barely covered over. Six pounds of seed will be sufficient for an acre; the young plants must be preserved from cattle during the first year, and in the next they will be fit for cutting; which may be begun in October. The plants will continue to shoot till Christmas, and be fit for use till March. It is said, that an acre of ground will produce fifteen tons of this fodder; and that it will answer the same purpose as an equal quantity of hay. In some places there are mills for bruising it, and it is mixed with chopped straw in the proportion of an hundred of straw to a ton of *furze*. It is said, that the common English *furze* will grow upon the dry sands, that are in the neighbourhood of the sea, though subject to be washed sometimes by the water; this is a thing extremely worth the trying, as it would then be of the greatest advantage to those who have walls or banks near the sea, to plant it on them to preserve them.

This being a very unprofitable plant in respect of many others, it is often necessary to destroy it. This may be done by plowing and burning the bushes upon the land. Mowing the land well in countries where mure is plentiful, is also a very good way; and there is yet another much better, which is to make wood-land, not arable, of the place; to this purpose it is only necessary to sow or plant acorns at proper distances. The *furze* will shelter the acorns till the time of their growing up to two or three feet high, and then they will soon sprout and destroy all the *furze* and every other weed. See *Mr. Husbands*, p. 308.

FUSA, in the *Indian Music*, the name of one of the musical notes, frequently also called *chittora*, and by some *quaver*.

FUSANUS, in *Botany*, a name given by many authors to the shrub, more usually called *asynanthus*. See **SPINDLER**.

This was sometimes called *atrachis* by the Greeks, and hath both this and its Roman name *fusinus*, from its being of use for making the distaff, used by the women in spinning. Some have supposed that this was the same with the *asynanthus*, *asynanthus*, of Theophrastus and the Greek writers, but very erroneously. See **TRISTRACHANTHUS**.

FUSAROLE, in *Architecture*, a moulding, or ornament, placed immediately under the echinus, in the Doric, Ionic, and Composite, capitals.

The Italians call it *sfusole*; and the French, from whom we borrow it, *sfusole*.

The *sfusole* is a round member, carved, in manner of a collar, or chaplet, with oval beads. The *sfusole* should always infer exactly under the eye of the volute, in the Ionic capital.

FUSSE, or **FUSS**, in *Wool-work*, is that conical part, drawn by the spring, and about which the chain, or string, is wound.

The word is French; where it literally signifies a *spindle*. The spring of a watch is the first mover. It is rolled up in a cylindrical box, against which it acts, and which it turns round in unbending itself. The string, or line chain, which at one end is wound about the *fusse*, and at the other fastened to the spring-box, disengages itself from the *fusse*, in proportion as the box is turned. And hence the motion of all the other parts of the spring-watch.

Now the effort, or action, of the spring, is continually diminishing from first to last; and, of consequence, unless that inequality was rectified, it would draw the string with more force, and wind a greater quantity of it upon the box at one time than another; so that the movement would never keep equal time.

To correct this irregularity of the spring, nothing could be more happily contrived than to have the spring applied to the arms of levers which are continually longer as the force of the spring is weaker. This foreign assistance, always increasing as it is most needed, maintains the action and effect of the spring in an equality.

It is for this reason that the *fusse* is made of a conical figure. It is, which is immovable, is the series of the centres of all the unequal circumstances which compose

the

the surface of the *fusile*: according as the part of a firing, which is unwilling, is applied to a larger circumference, it is at a greater distance from the fixed point in the axis corresponding thereto; and, of consequence, the power which draws by this firing, viz. the spring, acts with the more advantage; the spring begins to draw from the vertex of the cone, the most disadvantageous part, because its own force is then the greatest.

If the action of the spring diminished equally, as the parallel bases of a triangle do; the cone, which is generated of a triangle, would be the precise figure required for the *fusile*: but, it is certain, the weakening of the spring is not in that proportion; and, of consequence, the *fusile* should not be conical.

In effect, experience shews, that it should not be strictly so; but that it be a little hollow toward the middle, i. e. the arm of the lever must be there a little shortened; because the action of the spring is not sufficiently diminished of itself.

It is a matter of enquiry, among geometricians, what the precise figure of the *fusile* should be; that is, what the curve is, by whose revolution round its axis, the solid, whose figure the *fusile* is to have, shall be produced.

M. Varignon has determined this curve. The axis of the *fusile* is also the axis of the curve, which is convex on the side toward the axis, and, of consequence, concave all the way on the other, or outer side; and the ordinates are the different distances at which the firing is to be with regard to all the successive fixed points of the axis.

The force of the spring multiplied by the arm of the lever it is applied to, each moment, being always to make an equal product; it follows, that when the solid of the curve shall be formed, an ordinate multiplied by the surface of the solid comprised between that ordinate and the greatest of all the ordinates, viz. that of the base, will always yield a product equal to that of any other ordinates multiplied in the same manner. For the ordinates are only arms of the lever; and the parts of the surface comprehended between them and the base are equal to the lengths of the firing which covers them, i. e. to the correspondent forces of the spring; which is what constitutes the equation and the essence of the curve.

FUSER, FUZE, or FUZE, in War, an appendage of a bomb or grenade shell, by which the powder, or composition, in the shell, is set on fire, to do the designed execution.

The word is French, and literally denotes a *spindle*.

The *fuse* is a wooden pipe, or tap, commonly made of dry beech-wood, and sometimes of horn-beam taken near the root, filled with wild-fire, or the like composition; and is designed to burn so long, and no longer, as is the time of the motion of the bomb or shell from the mouth of the mortar to the place where it is to fall, so that the *fuse* must be contrived, either from the nature of the composition, or the length of the pipe which contains it to burn just that time. *Fuses* are turned rough and bored at first, and then kept for several years in a dry place; the diameter of the hole is about a quarter of an inch, which does not go quite through, but leaves about a quarter of an inch at the bottom, and the head is made hollow in the form of a bowl. The composition for *fuses* is salt-petre three parts, sulphur one, and mealed powder three, four, and sometimes five, when it is required to burn quicker. This composition is drove in with an iron driver, whose ends are capped with copper to prevent it from taking fire, and as equally hard as possible; the last shovel-full being all mealed powder, and two strands of quick-match laid across each other are drove in with it, the ends of which are folded up into the bowl, and a cap of parchment is tied over it till it is used. When these *fuses* are drove into the loaded shell, the lower end is cut off in a slope, so that the composition may set fire to the powder in the shell, and they must have such a length as to burn nearly as soon as the shell touches the ground. When the distance of the battery from the object is known, the time of the shell's flight may be computed nearly; which being known, the *fuse* may be cut accordingly, by burning two or three, and making use of a watch or a firing weight for a pendulum, of such a length as to vibrate seconds or any given parts of time. If the *fuses* are to be kept for some time after they are drove, the top must be covered with a mixture of two parts of pitch, one of rosin, and three of bees wax; which will prevent any air from coming to the composition. Muller's Treat. of Artillery, p. 294, &c.

FUZE or FUZE, is also sometimes used to denote a FIRE-LOCK.

FUSIBILITY, that quality in metals, and minerals, which disposes them for **FUSION**.

Gold is more *fusible* than iron, or copper; but less so than silver, tin, and lead.

Borax is frequently mixed with metals, to render them more *fusible*.

VOL. II. N° 145.

FUSIL, in *Horology*, by the French called *fofies*, q. d. *spindle*, is a bearing of a rhomboidal figure, more slender than the *lozenge*; its upper and lower angles being more acute than the two middle ones. See *Tal. Horol.* fig. 42.

FUSIL, in the *Military Art*. See **FIRE-LOCK**.

FUSILE column, and marble: see the **SUBSTANTIVE**.

FUSILIERS, or FUSILLERS, in the *Military Art*, are soldiers armed like the rest of the infantry, but wearing caps like the grenadiers, though somewhat shorter. Of these there are three regiments in the English service; the royal regiment of Scotch *fusiliers* raised in 1678; the royal regiment of English *fusiliers* raised in 1685; and the royal regiment of Welch *fusiliers* raised in 1688-9.

The word is formed from the French *fusil*, a *fusil*, fire-lock.

FUSILUS, in *Botany*, a name given by some to the **RUSANUS**, a more common name for the *eurogenium*.

FUSILY, or FUSILE, in *Horology*, is when a field, or ordinar, is entirely covered over, or divided into *fusils*.

FUSION, the solution, or melting, of metals, minerals, &c. by means of fire; or the act of changing them from their solid state to a *flux*.

The word is derived from the Latin *fusus*, of *funde*, I pour out. Whence, also, *effusus*, *infusus*, *perfusus*, and *transfusus*; which see.

To give the ore its metallic form, they *fuse* it: when it is in *fusion*, the metalline substance being the heaviliest, sinks to the bottom of the furnace; the other terrestrial matters rising, in form of *scoria*, to the surface.

It is commonly imagined, that the *fusion* and metalline form of ores is wholly the effect of fire; and we have theories of fusibility founded on this principle; but it is a mistaken one. Fire, no doubt, is the principal agent; but fire, alone, is not sufficient. A mineral, or piece of metal not purified, being put alone in a crucible, melts with great difficulty, and never becomes a perfect metal: copper ore, for instance, being thus applied, its impure part forms a *scoria*, and vitrifies; the metalline part residing at bottom, under the appearance of a black regulus. To promote the *fusion* and separation, they mix coals, or stones, or cinders, or old *scoria*, along with the ore; the inflammable principle in which, by help of fire, fuses them perfectly, sets the heterogeneous part at liberty, and raises it to the top. See **FLUX**.

The general reason of *fusion* is pretty easily assigned. The firmness or solidity of a body arises from the force wherewith its particles cohere. And the cohesion of all bodies is as the quantity of contact in the component particles.

Now, the corpuscles of fire, entering with rapidity into the pores of the metal, agitate, and, by degrees, loosen, divide, and diminish their contact; till at length there is not enough to hinder their rolling over each other, and giving way upon the least impulse.

The dilatation observable in all *fusions*, is a proof that the particles of the bodies are separated, and set at a distance from each other; and, consequently, their contacts and cohesions diminished.

In effect, rarefaction and dilatation are the necessary consequences of fire and heat.

From the difference of cohesion proceeds that variety we observe in the *fusions* of bodies: for such as have least contact of parts, soonest give way to the fire; and some will melt away by the warmth of a vapour only: thus air and mercury are so fusible, that the heat of the atmosphere is always sufficient to keep them fluid; when others, which have a stronger contact, are not to be separated without much difficulty. Upon this account, vegetables very easily diffuse, minerals flower, and metals flowest of all; and of the last, those wherein the contact of parts is least, as in lead and tin, melt readily melt; but those which are most compact, as gold and silver, are not to be managed but by a violent heat.

If now the force of cohesion were proportional to the quantity of matter, or to the weight of bodies, we might from statics account for all the variety that occurs in *fusion*: for by knowing the specific gravity of a body, we should then know what force is required to melt it; but because the same quantity of matter may be so variously disposed, that in one body there shall be a much greater contact than in another, though the gravity be equal or even greater in the latter, therefore the force of the cohesion cannot be eliminated by gravity; for lead though more ponderous than all other metals except gold, yet in the fire is more easily melted than almost any other; so that it necessarily follows, that in this metal there must be a less cohesion, or contact of parts, than much softer it may exceed others in the quantity of its matter.

Bodies after *fusion* return again into a solid mass, upon removing them from the fire; because their particles hereupon approach nearer to one another by their attractive force, and are compelled to unite.

Such as consist of homogeneous and unalterable parts; as wax, gums, and the purer metals, recover their ancient form: for when the same mixture of parts remains in the whole body, it must of course reassume the same appearance, when the separating power ceaseth to act; but other bodies, whose parts with respect to density and surface are extremely different from one another, while some are carried off by the force of heat, and others are changed as to figure and position, must be forced to appear in another form: for they cannot recover their original phases, unless every particle could reinitiate itself in that very situation it had before, which may be hindered infinite ways; as may be experienced easily in heterogeneous bodies.

The difference, therefore, observed even in homogeneous bodies after liquefaction, is no ways to be accounted for but from the changeableness of surface in their parts: for those bodies whose parts constantly retain the same surfaces, never lose their form; but others, by having the surfaces of their parts altered, have a different texture, and put on another appearance.

It had been formerly an opinion, very generally received that the solution of metals by lightning is effected by a kind of cold *fusum*; and the instances that have been usually alleged in support of this opinion, are those of a sword being melted in its scabbard, and of money being melted in a bag, whilst the scabbard and bag remained unharmed. But it appears, by a variety of experiments and observations, collected in the progress of ELECTRICITY to its present advanced state, that this kind of *fusum* is attended with heat and ignition, as in the case of common *fusum*. Phil. Trans. vol. li. part i. art. 30 and 31.

FUST, in *Architecture*, the shaft of a column; or that part comprehended between the base and the capital; called also the *naled*.

The word is French, and literally signifies a *shaft*.

The *fust* is that cylindrical part, which makes, as it were, the body or trunk of the column, exclusive of the head and foot.

FUSTIAN, in *Commerce*, a kind of cotton stuff, which seems, as it were, quilted, or whaled on one side.

Menage derives the word from *fustanum*, which in the corrupt Latin writers is used in the same sense, and is supposed to be formed from *fustis*, on account of the tree whereon the cotton grows. Bochart derives it from *fustat*, which, in Arabic, signifies the ancient city of Memphis, where cotton is produced in great abundance. Right *fustians* should be made altogether of cotton thread both woof and warp.

There are *fustians* of divers kinds, wide, narrow, coarse, fine, with flag or knap, and without it. There are also a great many made, whereof the warp is flax, or even hemp.

FUSTIAN, in *Criticisms*, a word used to express bombast.

FUSTICK, or **FUSTOCK**, a yellow wood used by the dyers.

The colour it yields is a fine golden yellow; but there should be some other ingredients mixed with it, to make it lasting. The tree that yields it grows in all the Caribbee islands; particularly in Barbadoes and Tobago, where it rises to a great height.

The dyers use it chiefly for **BLACK**; but some of the ablest and honestest among them, who would dye none but the best and most lasting colours, are of opinion it should be absolutely excluded out of all dying.

Beside this, there is another kind of *fustick* or *fustish*, growing in Italy, Provence, &c. which is used to dye a coffee-colour.

FUSTIGATION, in the *Roman Customs*, a punishment inflicted by beating with a cudgel. This punishment was peculiar to freemen; for the slaves were scourged or lashed with whips.

FUSTIGATION, *fustigatio*, is also a penance enjoined by the Roman inquisition.

FUSTUARIUM, in *Antiquity*, a Roman punishment, the same with **FUSTIGATION**.

FUSTUC, in *Botany*, a name given by some of the old writers to the tree which produces the pistachia-nuts. The word sounds so like the name of a wood used in dying, and called at this time *fustick*, that it might be supposed to express some tree of the same kind; but it is of a very different origin. The Jews and Arabians have called the pistachia-tree *fistic* and *fustack*, and from thence some have written the name *fustuck* or *fustine*; the Greeks have written it *πύστος*, and the barbarous Latin writers *fusticio*, which sounds very like the name **FISTACHIO**.

FUT-FA, in *Music*. See **F** and **CLER**.

FUTLOCKS, in a *Ship*, the timbers raised over the keel, or the compassing timbers which make her breadth. Those next the keel are called *ground-futlocks*, and the rest *upper futlocks*.

FUTLOCK, *futlocks*. See **SHROUDS**.

FUTURE, something to come hereafter.

We say a *future* state, a *future* contingency; there is none but God to whom *future* things are present.

FUTURE, or **FUTURE TENSE**, in *Grammar*, denotes an inflexion of verbs, whereby they denote, that a thing will be in some time yet to come. As, the last day will come: I shall see an end.

The *future* time admits of two cases: either we may intend to express a thing that shall come to pass in a short time; or a thing that shall happen in any indefinite time. Thus the Greeks have their *παῦλο ποτὶς* *futurum*, *πῶς ἂν* *possibile*, which marks a thing just going to be done as *ἔτι* *ἔτι*; besides the common, indefinite *future*, *ἔτι*, *I will do it*; *scribam*, *I shall write*.

In Latin, Italian, French, and even in English, the *future* of the indicative expresses only the design or intention of doing a thing, or simply that the thing will be done, as, I will praise, I will be approved; and the *future* in the subjunctive shews, that the thing will be done under certain circumstances; when I shall have seen Versailles, I will tell you. Sometimes the *future* is expressed in English by the present; If I meet your friend, I will send him to you; *si offendero*, *si insidero*, &c.

Mr. Harris, in his distribution of tenses, reckons three definite *future* tenses, besides the common indefinite *future*, which he calls the *aorist* of the *future*, viz. the inceptive *future*, as *scripturus ero*, I shall be beginning to write; the middle or extended *future*, as *scribens ero*, I shall be writing; and the completive *future*, as *scripsero*, I shall have done writing. See **TENSE**.

FUZE, or **FUZEL**. See **FUSEL**.

FUZEE, in the *Manege*, two dangerous splints, joining from above downwards: commonly a *fuzee* rises to the knee and lames the horse.

Fuzes differ from *scrows* or thorough splints in this, that the latter are placed on the two opposite sides of the leg. See **SPLENT**.

FUZILERS. See **FUSILIERS**.

G.

G, The seventh letter in our alphabet, and the fifth consonant: though in the alphabets of all the oriental languages, the Hebrew, Phœnician, Chaldee, Syriac, Samaritan, Arabic, and even

Greek, *G* is the third letter. The Hebrews call it *ghimel*, or *gimel*, q. d. *camel*; because it resembles in its form the neck of that animal; and the same appellation it bears in the Samaritan, Phœnician, and Chaldee: in the Syriac it is called *gimel*, in Arabic *ghim*, and in Greek *gamma*.

The letter *G* is of the mute kind, and cannot be any way sounded without the help of a vowel. It is formed by the reflection of the air against the palate, made by the tongue, as the air passes out of the throat: which Martiano Capella expresses thus, *G spiritus cum palato*, so that the *G* is a palatal letter.

G in English has two sounds, one from the Greek *Γ*, and the Latin, which is called that of the hard *G*, because it is formed by a pressure somewhat hard of the fore-part of the tongue against the upper gum; which sound it retains before *a*, *e*, *i*, *u*, *l*, *r*, as *gate*, *gay*, *pull*. At the end of a word it is always hard, as *ring*, *page*, &c. The other sound, called that of the soft *G*, resembles that of *j*, and is commonly, though not always, found before *e* and *i*, as in *gen* and *gibbet*. To this rule, however, there are many exceptions; *G* is often hard before *i*, as *give*, &c. and sometimes before *e*, as *ger*, &c. It is also hard in derivatives from words ending in *g*, as *singing*, *stranger*, &c. and generally before *er*, at the end of words, as *finger*. *G* is mute before *n*, as *gnash*, *sign*. *G* has the sound of the hard *G* in the beginning of a word, as *ghostly*, in the middle, and sometimes at the end it is quite silent, as *right*, *though*. At the end of a word *G* has often the sound of *f*, as *laugh*. Johnson.

The Latins took the liberty to drop the letter *G* at the beginning of words, before an *n*, as in *gnatus*, *gnusco*, *gnobili*, *gnarri*, &c. which they ordinarily wrote *natus*, *nusco*, *nobili*, &c. They also frequently changed it into *c*, as *gaulus*, into *canelus*; *gregarius*, *graculus*; *quingentum*, *quincientum*, &c. Sometimes it was put instead of *n*, before *a*, *e*, and for another *c*, as *Agathis*, *aggru*, *agguilla*, &c. for *Agathis*, *ancora*, *anguilla*, &c. And instead of *p*, as *magalia*, for *mapalia*, &c. *G* is also used instead of *q*, and *g* instead of *q*, as in *anguina*, *anguis*, *anguina*, &c. instead of *r*, as in *apagium*, for *apagium*; *aggr*, for *arrey*, &c. And instead of *l*, as in *spargu*, *sparsi*, *spargum*, or rather, it is retrenched from those last words, to avoid the cacophony of *sparsi*, or *sparsi*. *G* is also put for *c*, as in *Gaius*, for *Gaius*; *Caius*, for *Gaius*; *Gasta*, for *Gaieta*; and for *v*, as in *figura*, for *fuera*. See N, P, &c.

The northern people frequently change the *G* into *v*, or *w*, as in *Gallus*, *Wallus*; *Gallia*, *Wallia*, *Valia*, &c. For in this instance it must not be said that the French have changed the *w* into *G*; because they wrote *Gallus* long before *Wallus*, or *Wallia*, were known, as appears from all the ancient Roman and Greek writers. And yet it is equally true, that the French change the *w* of the northern nations, and *v* consonant, into *G*; as *Willhelmus*, *William*, into *Gaillanus*; *Walpurgis*, into *Gulphidus*; *Vassus*, into *Galsen*, &c.

Diomed. lib. ii. cap. De Litera, calls *G* a new letter; his reason is, that the Romans had not introduced it before the first Punic war; as appears from the rollral column, erected by C. Duilius, on which we every where find a *c* in lieu of *G*. It was Sp. Carvilius who first distinguished between those two letters, and invented the figure of the *G*; as we are assured by Terentius Scaurus. The *c* served very well for *G*; it being the third letter of the Latin alphabet, as the *G* or *y* was on the Greek.

The *G* is found instead of *c* on several medals: Vaillant,

Num. Imperat. tom. i. p. 39. M. Beger produces a medal of the Familia Ogulnia, where *GAR* is read instead of *CAR*, which is on those of M. Patin. But the *c* is more frequently seen on medals, in lieu of *G*, as *AUGUSTALIS CALLARICA CARTACINENSIS*, &c. for *AUGUSTALIS*, &c. Not that the pronunciation of those words are altered, but only that the *G* was unartfully or negligently cut by the workmen; as is the case in divers inscriptions of the Eastern empire; where *AVE*, *AUCC*, *AUCCO*, were frequently found for *AUG*, &c.

The form of our *G* is taken from that of the Latins, who borrowed it from the Greeks; the Latin *G* being certainly a corruption of the Greek gamma, *Γ*, as might easily be shown, had our printers all the characters and forms of this letter, which we meet with in the Greek and Latin MSS. through which the latter passed from *Γ* to *G*.

As to the gamma of the Greeks, it is manifestly the *γ* of the Hebrews or Samaritans. All the difference between the gamma and phœnic confists in this, that the one is turned to the right, and the other to the left, according to the different manners of writing and reading, which obtained among those different nations; so that all the pains Salmastus has taken on Solinus, to prove that the *G* was derived from the Greek kappa, are lost.

G, as a Roman abbreviature, has various significations. It denotes *gratias*, *geni*, *gaudium*, &c. *G. V.* signifies *genia urbis*, and *G. P. R.* *gloria papae Romani*.

G has also been used as a numeral letter, signifying 400; according to the verse,

G quadringentes demonstrativa tensile.

When a dash was added at the top, *G̃*, it signified forty thousand.

G, in Chronology, is the seventh dominical letter.

G, on the French Coins, denotes the city of Poitiers.

G is also used, in Music, to signify one of the clefs; viz. that of the highest part, called the *treble*, or *alt*. See CLEF, and TREBLE.

GABALE, in *Afychology*, a deity worshipped at Heliopolis under the figure of a lion, with a radiant head; and it is thus represented on many medals of C. rullus.

GABARDINE, from the Italian *garbardina*, has been sometimes used to denote a coarse frock, or mean dress. In this sense it is used by Shakespeare in his Tempest and Merchant of Venice, and by Butler in his Hudibras, book i.

GABBARA, a name which the Egyptians gave the dead bodies which they kept by them, instead of burying them.

That people, out of a custom which they had received from their ancestors, and which arose in some measure from the position of their country, which is exposed to the inundations of the Nile, used to wrap up the bodies of persons of eminence, particularly those of saints and martyrs, in a great number of linen cloths, with balsam and spices; and instead of interring them, they preserved them in their houses: thinking, that thereby they did them much more honour. See EMBALMING, and MUMMY.

And these, St. Augustine tells us, were what they called *gabbaras*. Sermon cxx. de diversis, cap. 12.

Pliny makes mention of the same thing, lib. vii. cap. 16, where he relates, that in the time of Claudius, a *gabbara* was brought from Arabia, almost ten feet long.

The word is Arabic, Syriac, and Hebrew, formed of *gabbar*, a man, and denotes an embalmed body.

GABEL, or **GABELLE**, in the French Customs, a duty or imposition on salt.

Etymologists are divided as to the origin of the word.

Some

by some of the old writers to the *TRIDRUM*, or, as we usually call it, oil of petre.

GAFET, in the *Matrua Media* of the *Arabians*, a name given by Avicenna and others to the farcicola of the Greeks.

GAFF, in *Sea-Language*, a sort of boom or pole used to extend the upper edge of the mizen; the foremost or inner extremity of it is furnished with two cheeks, forming a semi-circle, which include the after-part of the main, so as to confine the *gaff* close to its respective mast whilst the sail is hoisting or lowering.

GAFFS. See **GABIOCKS**.

GAFOLD-land, or *Garut-land*, *terra fœdalis*, in our old Writers, land liable to taxes, and rented or let for rent.

GAGATES. See **JET**.

GAGATRONICA, a word used by the *Writers of the Middle Age*, as the name of a distinct stone, but meaning only a false spelling of the word *GAGATRONIUM*.

GAGE, in our ancient *Customs*, signifies a pledge, or pawn, given by way of security.

The word is only properly used in speaking of moveables: for immovables, the term *hypotheca* is used.

If the *gage* perish, the person who received it is not to answer for it, but only for extreme negligence, &c.

GAGE is also used for a challenge to combat.

In this sense it was a pledge, which the accuser, or challenger, cast on the ground, and the other took up, as accepting the challenge: this was usually a glove, gauntlet, chaperon, or the like.

The Grand Customary mentions *gages pîgés de duel*.

These were gentlemen of the relations or friends of the combatants. If he who had given the *gages pîgés* was overcome, he was to pay a *malice* agreed on.

GAGE is only now retained as a substantivè; as a verb, the *g* is changed into *w*; and of *gage* is formed *wage*. As, to *wage* law, to *wage* deliverance, *q. d.* to give security a thing shall be delivered.

If a person who has distrained be sued for not having delivered what he had took by distress, he should *wage*, or *gage*, or *gage*, deliverance; that is, put in surety that he will deliver them.

GAGE, *mort*, *marum nudum*, is that which is left in the hands of the proprietor, so that he keeps the fruits thereof: in opposition to *vifage*, *erum nudum*, where the fruits or revenues are reaped by the creditor, and reckoned on the foot of the debt, which diminishes in proportion thereto. The second acquits or discharges itself, and as it subsists, furveys the debt, and is therefore called living pledge; the first does not.

Pomey also uses *MORT-GAGE* for the possession of any effects, on condition of surrendering them up at the good pleasure of the person who gave them.

GAGE, in the *Sea Language*. When one ship is to windward of another, she is said to have the *windward-gage* of her.

The seamen, also, call trying how much water a ship draws, *gaging*, or rather *gaging* of her; and it is done thus:

They drive a nail into a pike, near the end, and then put down this pike by the rudder, till the nail catch hold under it; for then, as many feet as the pike is under water is the ship's *gage*, or depth of water the draws.

GAGE, in *Survey*, is an instrument made to strike a line truly parallel to the straight side of any board, or piece of stoff.

Its chief use is for *gaging* of tenons true, to fit into mortises; and for *gaging* stuff of an equal thickness.

It is made of an oval piece of wood, fitted upon a square stick, to slide up and down freely thereon, and with a tooth at the end of a staff, to score, to strike a line upon the stuff at any distance, according to the distance of the oval from it.

GAGE, among *Letter-founders*, is a piece of box, or other hard wood, variously notched which is used to adjust the dimensions, slopes, &c. of the different sorts of letters. There are several kinds of these *gages*. See **FOUNDRIERY**.

GAGE, in *Pneumatics*, is of various sorts, according to the purposes to which it is applied. Thus,

GAGE of the air-pump. See **AIR-PUMP**. The extraordinary powers of exhaustion in Mr. Smeaton's air-pump, as they are indicated by his *pear-gage*, have lately been considered with peculiar attention by Mr. Nairne, F.R.S. He was led to prosecute a series of experiments on this subject, by observing the remarkable difference between the indications of exhaustion and rarefaction by this *gage*, and by the common barometer *gages*. Having used every possible precaution in preparing his different *gages*, he nevertheless found, that, when they were put under a receiver, placed on a leather dressed in alum, and soaked in oil and tallow, according to his usual method,

and the pump was worked for ten minutes, the quicksilver in the barometer *gage* rose to within one tenth of an inch of the height of the quicksilver in the standard barometer, which was at that time of thirty inches, and indicated that the air had been rarefied only about three hundred times; whereas Mr. Smeaton's *pear-gage* indicated a degree of exhaustion equal to six thousand times, the whole of its cavity, on dipping its open end into the cup of quicksilver and letting in the air, except a six thousandth part, being filled by the quicksilver. The difference of indications by these two *gages* was found much more considerable in subsequent experiments. Having an opportunity of repeating some of these experiments before the honourable Henry Cavendish, Mr. Smeaton, and others, in April 1776, Mr. Cavendish accounted for the observed and astonishing difference, by referring to some experiments of his father, Lord Charles Cavendish, from which it appeared, that water, whenever the pressure of the atmosphere on it is diminished to a certain degree, is immediately turned into vapour, and reduced as suddenly to water again on retuning the pressure; the degree of pressure varies according to the temperature of the water; for when the heat is 72° of Fahrenheit's scale, it turns into vapour as soon as the pressure is reduced to that of three quarters of an inch of quicksilver, or about one fortieth of the usual pressure of the atmosphere; but when the heat is only 41°, the pressure must be reduced to that of a quarter of an inch of quicksilver, or to one hundred and twentieth of the usual pressure, before the water turns into vapour. According to this theory, whenever the air in the receiver is exhausted to the above mentioned degree, the moisture adhering to the different parts of the machine, will be converted into an elastic vapour, and supply the place of the air, which is drawn away by the working of the pump; and the fluid left in the receiver and *pear-gage* will be chiefly this vapour. When the air is let into the receiver, the vapour within the *pear-gage* will be reduced to water, and only the real air will remain uncondensed; and therefore this *gage* only shows how much real air is left in the receiver, and not how much the pressure or spring of the included air is diminished; whereas the barometer *gage* shows how much the included fluid is diminished, and that equally, whether it consists of air or vapour. In order to ascertain the truth of this plausible theory, Mr. Nairne proceeded to try every part of his apparatus as much as possible from any adhering moisture, concluding that by this means he should be able to bring the two *gages* to an agreement. Instead of placing the receiver on leather, as before, he put it on the pump-plate, made as clean and dry as possible, and applied a cement round its edge to exclude the outward air. When the pump in this state was worked for ten minutes, the barometer *gage* indicated a degree of exhaustion nearly equal to six hundred; and, on letting the air into the receiver, the *pear-gage* indicated a degree of exhaustion little more than six hundred also. In another experiment he put a piece of the dried leather above mentioned in the receiver, and found, on working the pump, that the barometer *gage* indicated a degree of exhaustion of nearly three hundred, but the *pear-gage* indicated a degree of exhaustion not less than four thousand. But on taking out the piece of leather, and repeating the experiment, the two *gages* agreed, as before. Having thus concluded, in general, that a considerable quantity of vapour arose from the compound of leather, alum, oil, and tallow, it was his next object to find out from which of these substances the vapour was principally derived. For this purpose he separately and successively included in the receiver two ounces of tallow, the same quantity of oil and of alum, and a piece of leather as it comes from the leather-sellers, weighing a hundred grains; from these experiments he found that the elastic vapour, which occasioned so great a difference in the testimony of the *gages*, arose chiefly from the leather, and very little from the tallow, oil, and alum. In the experiment with the leather, it supplied the place of the exhausted air in fact, that he could not in ten minutes make the barometer *gage* indicate a degree of exhaustion of more than a hundred and fifty-nine; whereas that of the *pear-gage* was a hundred thousand. In order to determine whether the difference in the *gages* was occasioned by the moisture of the leather, Mr. Nairne repeated the experiment with a piece of fresh leather, weighing a hundred grains. The *pear-gage* indicated a rarefaction of a hundred thousand, and the leather had lost two grains of its weight; when the same piece of leather was so thoroughly dried by the fire till it would lose no more of its weight, and thus reduced to eighty grains, it gained two grains in the experiment, and the *pear-gage* exhibited a rarefaction only of two hundred and eighty. The leather was afterwards held in the

steam of hot water till it had regained its former moisture and weight, and the degree of exhaustion indicated by the *pearl-gage* was a hundred thousand, and the loss of weight two grains, as before. In the first of these experiments, the degree of rarefaction indicated by the *barometer-gage* was a hundred and thirty-four; in the second, two hundred and sixty-eight; and in the third, one hundred and forty-seven. The effect of the vapour arising from small quantities of different fluids, and from other substances containing moisture, was tried in a variety of instances; and having found that the small quantity of moisture which exhaled from the substances under the receiver, prevented the pump from exhausting to a considerable degree, Mr. Nairne suspected that whenever wet leather had been used to connect the receiver with the plate, there must have arisen to great a quantity of vapour as to have prevented the degree of exhaustion from being near so great as in other instances. This led him to another set of experiments, in order to ascertain this fact. Having first placed the receiver on the pump-plate, made clean and dry, with only a little oil poured round the outside edge of it, both *gages* agreed in indicating a rarefaction of six hundred, as before; but when the receiver was fit on leather, that had been soaked for two days in water, the rarefaction indicated by the *barometer-gage* was uniformly fifty-one in three different trials; but the *pearl-gage* exhibited first sixteen thousand, in the second instance fifteen hundred, and in the third one thousand, when the receiver was placed on a piece of leather, soaked in a mixture of water and spirit of wine, the *barometer-gage* in three trials always indicated a degree of exhaustion equal to forty-seven; but the *pearl-gage* was anomalously various, in the first trial being twelve thousand; in the second, eleven hundred and fifty; and in the third, five hundred. By these experiments it sufficiently appears, that the use of leather soaked in water, or in water and spirit of wine, prevents the pump from exhausting to any considerable degree. By two other experiments, in which water was used for softening the leathers of the pistons of a common air-pump, we find that the highest degree of rarefaction that could be procured was thirty-seven, according to the *barometer-gage*, and thirty-eight, according to the *pearl-gage*. Mr. Nairne's last experiment furnishes a very extraordinary evidence of the effect of vapour on the *barometer-gage*: having put a phial of ether under the receiver, in order to produce artificial cold, and working the pump for half an hour, the degree of exhaustion indicated by the *barometer-gage* was only sixteen; though the same pump exhausted above four hundred times before the ether was put under the receiver. The degree of cold produced by means of ether, in the exhausted receiver, was 4° below 0 in Fahrenheit's scale, or 39° below 55° , which was the temperature of the air in the room where the experiment was made. Phil. Transact. vol. LXVII. part II. art. 32. page 614; &c.

GAGE of the barometer, is a contrivance for estimating the exact degree of the rise and fall of the mercury in the Torricellian tube. It is well known, that whilst the mercury rises in the tube, it sinks in the cistern, and vice versa; and, as the distance between the divisions graduated on the annexed scale and the surface of the mercury in the cistern is not truly shown by the numbers on the scale, errors must happen in determining the precise height of the mercury. To remedy this inconvenience, a line is cut upon a round piece of ivory, which is fixed near the cistern: this line is accurately placed at a given distance from the scale; e. g. twenty-seven inches; and a small float of cork, with a cylindric piece of ivory fixed to its upper surface, on which a line must be cut at the distance of two inches, exactly from the under surface of the cork, is left to play freely on the quicksilver, and the cylinder works in a groove made in the other piece: from this construction it appears, that if these marks are made to coincide, by raising or lowering the screw which acts on the quicksilver, then the divisions on the scale will express the true measure of the distance from the surface.

GAGE of the condenser, is a glass tube of a particular construction, adapted to the condensing engine, and designed to shew the exact density and quantity of the air contained at any time in the condenser. For this purpose, let *D* *Fig. 1*, *Tab. II. Pneumatica*, fig. 22. be a small glass tube, about one ninth of an inch in diameter, open at *D*, but hermetically sealed at *E*; *DE* a larger tube, hermetically sealed at *D*, and containing at that end a quantity of mercury, which takes up two or three inches in length, and covers the open end of the smaller tube; the other end *C*, of the larger tube, is strongly cemented into the brass elbow-piece *O* *E*, at *C*, *Fig. 23*, so as not to be quite at right angles with *OA*, but to incline a little downwards, that the mercury at *D* may not run

towards *C*, and pass into the condensing glass *GB*. This *gage* is screwed on at *s*, and the injecting syringe at *O*, a cock being interposed at *O* or *s*, or not used at all, according to the nature of the experiment. Whilst air is injected into the condensing glass, and the large tube of the *gage* at the same time, the air in the smaller tube, which has no communication with the injected air, must be rarer and weaker; and, therefore, the mercury at *D* will enter the tube, and advance in it, in proportion to the condensation of the air in *GB*. In *Fig. 22*, *d*, *e*, *f*, *g*, represent three rings of spring wire, at such distances as to shew, by the motion of the mercury in the small tube, when the density of the air is doubled, tripled, or quadrupled; because the air, which at first filled the whole small tube, now takes up only the spaces *cd*, *ce*, *ef*; or in Mr. Haukbee's style, one, two, or three atmospheres are thrown in.

Another kind of *gage* may be put within the condensing glass, at the bottom of it, when the use of the preceding *gage* would be inconvenient. This is a short cylinder of wood, *Fig. 24*, about an inch thick, with a hole through its middle between *a* and *b*, of about $\frac{1}{8}$ inch in diameter; the outward diameter of the cylinder must be about four inches, so that the cylinder may easily stand within the condensing glass on the plate, supporting its bottom at *h*, *Fig. 23*. There is a hole at *A* of about $\frac{1}{2}$ of an inch in diameter, and $\frac{1}{2}$ of an inch deep, filled with mercury; *a*, *e*, *b*, *b*, is a small glass tube, open at *a*, but hermetically sealed at *b*, and bent to a right angle at *c*, the middle of the distance between *a* and *b*. When the open end *a* is immersed in mercury, and the air on the surface of the mercury condensed, the air in the tube will recede towards the elbow *c*, and the mercury, following it, then to what degree it is condensed. When the mercury is at *c*, then one additional atmosphere bears upon its surface, and two atmospheres, if it be come to *d*; which places are marked by rings of springing brass wire; at *a* and *b*, about an inch of the ends of the tube are bent to a right angle, that the end *a* may go into the wood, whilst the end *b* goes under the surface of the mercury, where it is held by a cork, whilst air is injected into the condensing glass. Delisle's, Exp. Phil. vol. II. p. 394, &c.

GAGE, for SET ALTITUDE.

GAGE, bucket for, an instrument contrived by Dr. Hales, to find the different degrees of coolness and faleness of the sea, at different depths: it consists of a common household pail or bucket, with two heads. These heads have each a round hole in the middle, about four inches in diameter, covered with square valves opening upward; and that they may both open and shut together, there is a small iron rod, fixed to the upper part of the lower valve, and the other end to the lower side of the upper valve. So that as the bucket descends with its sinking weight into the sea, both the valves may open by the force of the water, which by that means has a free passage through the bucket. But when the bucket is drawn up, then both the valves shut by the force of the water at the upper part of the bucket; so that the bucket is drawn up full of the lowest sea water to which it has descended.

When the bucket is drawn up, the mercurial thermometer fixed in it is examined; but great care must be taken to observe the degree at which the mercury stands, before the lower part of the thermometer is taken out of the water in the bucket, lest it be affected by the different temperature of the air.

In order to keep the bucket in a right position, there are four cords fixed to it, reaching about three feet below it; to which the sinking weight is fixed.

The result of several trials with this *gage* was, that, when it was let down to different depths, from 300 feet to 5340 feet, in lat. $25^{\circ} 13' N$. and long. $25^{\circ} 12' W$. it was discovered by the thermometer, that the cold increased gradually in proportion to the depths, till it descended to 3900 feet, viz. near $\frac{1}{2}$ of a mile, whence the mercury in the thermometer came up at 53° ; and though it was afterwards sunk to 5340 feet, i. e. a mile and 60 feet, it came up no lower: the warmth of the water upon the surface, and that of the air, was all that time 85° .

When the water in the bucket was become of the same temperature with that on the surface of the sea, equal quantities of both were weighed and tried by the thermometer: that from below was found to be the heaviest, and, consequently, the densest. See Treatise on Ventilators, part II. p. 122, &c.

Dr. Hales was probably led to the construction of this *gage* from an instrument invented by Dr. Hook, and designed for the same purpose. This consists of a square wooden bucket, *C*, *Tab. Miscellanea*, *Fig. 16*, whose bottoms are so contrived, that, as the weight *A* sinks the

Iron B, to which the bucket C is fastened by two handles D, D, on the end of which are the moveable bottoms or valves E, E, and thereby draw down the bucket, the resistance of the water keeps up the bucket in the posture C, whereby the water, whilst the bucket is descending, hath free passage through it; whereas, as soon as the bucket is pulled upwards by the line F, the resistance of the water to that motion beats the bucket downwards, and keeps it in the posture G, whereby the included water is kept from getting out, and the ambient water kept from getting in. Phil. Trans. N^o 9, p. 149. and N^o 24, p. 447. or abt. vol. ii, p. 250.

GAGE, *aquamaris*, is the name of an apparatus contrived by Dr. Hales, and applied, in various forms, to the branches of trees, in order to determine the force with which they imbibe moisture. See *Arb. Med. Utilis*, fig. 27, be a cylindrical glass, c. gr. of an inch diameter within, and eight inches long. Into this glass is introduced the branch of a young thriving apple tree *b*, about three feet long, with latent branches; the diameter of the transverse cut *a* being $\frac{1}{2}$ of an inch. Having fitted the joint *a* to the tube *a*, by folding a piece of sheep's skin round the stem, it is cemented with a mixture of bees-wax and turpentine melted together in such a proportion, as to make a very stiff clammy paste when cold, and over the cement rolls of wet bladder are bound firmly with packthread. To the lower end *e* of the large tube, a smaller tube *x*, is cemented, being about $\frac{1}{4}$ of an inch diameter, and sixteen inches long, and in substance full of $\frac{1}{2}$ of an inch thick. These tubes are cemented together at *e* with common hard black dust or powdered chalk cement, and the joint is further secured with the cement of bees-wax and turpentine, over which a wet bladder is bound. The apparatus being thus prepared, the branch is turned downwards, and the glass tube upwards, and then both tubes are filled with water; with the finger applied to the open end of the small tube, it is inverted and immersed in the glass cistern *a*, full of mercury and water. In this situation the lower end of the branch was immersed six inches in water, viz. from *r* to *s*; the water was imbibed by the branch at its transverse cut *r*, and during its ascent into the sap-vessels of the branch, the mercury rose in the tube *e* from the cistern *a* to that in half an hour it was risen $\frac{1}{2}$ inches high, as far as *x*. The height of the mercury indicated, in some measure, the force with which the sap was imbibed, though not the whole force; because, while the water was imbibed by the branch, its transverse cut was covered with innumerable little hemispheres of air, and many air-bubbles issued out of the sap vessels, which partly filled the tube *e*, as the water was drawn out of it; and, therefore, the height of the mercury could only be proportionable to the excess of the quantity of water drawn off above the quantity of the air, which issued out of the wood. If the quantity of air, issuing from the wood, had been equal to the quantity of water imbibed, it is plain that the mercury could not rise at all, because there would be no room for it in the tube; but, if more parts in twelve of the water be imbibed by the branch, and only three such parts of air issue into the tube in the same time, the mercury must rise near six inches, and so proportionally in other cases. Dr. Hales observed, that the mercury rose highest, in most cases, when the sun was clear and warm, and that it subsided three or four inches towards evening, but rose again the next day as it grew warm, though seldom to high as at first. Dr. Hales adapted the size and shape of the glass apparatus to a great variety of branches of several trees and of different kinds of trees, and repeated the experiment above described, *matris munitio*, in a variety of instances. See his *Vegetable Statics*, vol. i. chap. ii. p. 84, &c.

GAGE, *gaging*, is a tool used by mathematical instrument makers, for measuring and setting off distances: it consists of a beam, tooth, sliding socket, and the shoulder of the socket.

GAGE, *gale*, is the name of an instrument used for determining the height of the tides by Mr. Bayly, in the course of a voyage towards the South-pole, &c. in the Resolution and Adventure, in 1771, 1772, 1773, and 1775.

This instrument consists of a glass tube, whose internal diameter was seven tenths of an inch, lathed fast to a ten feet fir rod, divided into feet, inches, and quarters: this rod was fastened to a strong post fixed upright and firm in the water. At the lower end of the tube was an exceeding small aperture, through which the water was admitted. In consequence of this construction, the surface of the water in the tube was so little affected by the agitation of the sea, that its height was not altered one tenth of an inch, when the swell of the sea was two feet; and Mr. Bayly was certain, that with this instru-

ment he could discern a difference of one tenth of an inch in the height of the tide.

GAGE, *gater*. See *ALTIMETER* and *HYDROMETER*.

GAGE, *weather*, is *Wool-language*. See *GAGE*, above.

GAGER *de ley*. See *WAGER* of law.

GAGER, and **GAGING**, in *Geometry*. See **GARGER**.

GAGING, in *Geometry*. See **GARGER**.

GAGNOLA, in *Libology*, a name given by the Spaniards to a species of the acari, or syngnathus of Aristotle. The particular species meant by it, is that called by Aristotle, the hexagonal bodied syngnathus with the pinnated tails; others call it the *scus Aristotelis*, or *acari scuntis*, and the French the trumpet-fish; we call it sometimes the needle-fish, sometimes the trumpet-fish, and sometimes the tobacco-pipe-fish.

GAHALA, in *Botany*, a name given by some writers to the *calceola* or great Egyptian arum.

GAIANITES, **GAIANITES**, a sect of ancient heretics, sprung from the EPHESIANS.

This sect was of an older standing than Galen, a bishop of Alexandria in the fifth century, from whom, however, they took their name. They adhered to the opinion of Julian Hæcæmæus, the chief of the incorruptibles and Platonists, and came, at length, to be denominated *Gaianites*, upon Galen's putting himself at their head. They denied that Jesus Christ, after the hypochondriac union, was subject to any of the infirmities of human nature.

GAIDEROPHARUS, in *Libology*, a name given by some to a fish of the trutaceæ kind caught in the Mediterranean, and more usually called *CALLARIAS*.

GAIN, the profit, or lucre, a person reaps from his trade, employment, or industry.

Some derive the word from the German *gains*, whereof the Italians made *gainsio*; the French and English *gain*.

There are legal and reputable gains, as well as sordid and infamous ones. What is gained beyond a certain sum, by gaming, is all liable to be restored again; if the loser will take the benefit of the law.

GAIN, in *Architecture*, is the workmen's term for the bevelled shoulder of a joint, or other timber.
